The **middle sacral artery** is a small vessel, which arises from the back of the aorta, a little above its bifurcation. It descends in the middle line in front of the fourth and fifth lumbar vertebræ, the sacrum and coccyx, and ends in the glomus coccygeum (coccygeal gland); it is crossed by the left common iliac vein. Minute branches are said to pass from it to the posterior surface of the rectum. On the last lumbar vertebra it anastomoses with the lumbar branch of the ilio-lumbar artery; in front of the sacrum it anastomoses with the lateral sacral arteries, and sends offsets into the anterior sacral foramina.

COMMON ILIAC ARTERIES (figs. 638, 646)

The abdominal aorta divides, on the left side of the body of the fourth lumbar vertebra, into the two **common iliac arteries** which diverge from the termination of the aorta, pass downwards and lateralwards, and divide opposite the intervertebral fibrocartilage between the last lumbar vertebra and the sacrum, into two branches, the *external iliac* and *hypogastric arteries*: the former supplies the greater part of the lower extremity; the latter, the viscera and parietes of the pelvis, and the glutæal region.

The **right common iliac artery** (fig. 646), about 5 cm. long, passes obliquely across the body of the last lumbar vertebra. *In front* of it are the peritoneum, the small intestine, branches of the sympathetic nerves, and, at its point of division, the ureter. *Behind*, it is separated from the bodies of the fourth and fifth lumbar vertebræ, and the intervening fibrocartilage by the terminations of the two common iliac veins and the commencement of the inferior vena cava. *Laterally*, it is in relation, above, with the inferior vena cava and the right common iliac vein; below, with the Psoas major. *Medial* to it, above, is the left common iliac vein.

The **left common iliac artery**, about 4 cm. long, is in relation, *in front*, with the peritoneum, the small intestine, branches of the sympathetic nerves, and the superior hæmorrhoidal artery, and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebræ, and the intervening fibrocartilage. The left common iliac vein lies partly

medial to, and partly behind, the artery; laterally, the artery is in relation with the Psoas major.

Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas major, ureters, and the surrounding areolar tissue, and occasionally give origin to the ilio lumbar or to accessory renal arteries.

Peculiarities.—The point of origin of the common iliac arteries varies according to the bifurcation of the aorta, which in most cases occurs either upon the fourth lumbar vertebra, or upon the fibrocartilage between it and the fifth.

FIG. 646.—The arteries of the pelvis. Right side

The common iliac arteries may divide above or below the usual level.

The length of the arteries varies from 3.5 to 7.5 cm. In rare instances, the right common iliac has been found wanting, the external iliac and hypogastric arteries arising directly from the aorta.

Applied Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurysm or hemorrhage, implicating the external iliac or hypogastric arteries. The easiest and best method of tying the artery is by a transperitoneal route. The abdomen is opened, the intestines are drawn aside and the peritoneum covering the artery divided; the sheath is then opened and the needle passed from the medial to the lateral side. On the right side great care must be exercised in passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied, the incision in the peritoneum over the artery should be sutured.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are: the anastomoses of the hemorrhoidal branches of the hypogastric artery with the superior hæmorrhoidal

branches from the inferior mesenteric artery; of the uterine, ovarian, and vesical arteries of the opposite sides; of the lateral sacral arteries with the middle sacral artery; of the inferior epigastric artery with the internal mammary, lower intercostal, and lumbar arteries; of the deep iliac circumflex artery with the lumbar arteries; of the ilio-lumbar artery with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the inferior epigastric artery.

HYPOGASTRIC ARTERY (fig. 646)

The **hypogastric or internal iliac artery**, about 4 cm. long, arises at the bifurcation of the common iliac, opposite the lumbosacral articulation; it descends to the upper margin of the greater sciatic foramen where it divides into an *anterior* and a *posterior* trunk.

Relations.—It is in relation *in front* with the ureter; *behind*, with the internal iliac vein, the lumbosacral nerve-trunk, and the Piriformis muscle; *laterally*, near its origin, with the external iliac vein, which lies between it and the Psoas major muscle; lower down, with the obturator nerve.

In the fetus, the hypogastric artery is twice as large as the external iliac artery, and is the direct continuation of the common iliac artery. It ascends on the back of the anterior wall of the abdomen to the umbilicus, converging towards its fellow of the opposite side. Having passed through the umbilical opening, the two arteries, now termed *umbilical*, enter the umbilical cord, where they are coiled round the umbilical vein, and ultimately ramify in the placenta.

At birth, when the placental circulation ceases, the pelvic portion only of the artery remains patent and constitutes the hypogastric artery and the first part of the superior vesical artery of the adult; the remainder of the vessel is converted into a solid fibrous cord, the *lateral umbilical ligament* (obliterated hypogastric artery), which extends from the pelvis to the umbilicus.

Peculiarities.—The length of the hypogastric and common iliac arteries bear an inverse proportion to each other.

The place of division of the hypogastric varies between the upper margin of the sacrum and the upper border of the greater sciatic foramen.

Applied Anatomy.—The application of a ligature to the hypogastric artery may be required in cases of aneurysm or hemorrhage affecting one of its branches. The vessel is best secured by an abdominal section in the median line, the vessel being reached through the peritoneal cavity. It should be remembered that the vein lies behind, and, on the right side, a little lateral to the artery; the ureter lies in front of it.

Collateral Circulation.—The circulation after ligature of the hypogastric artery is carried on by the anastomoses of the uterine and ovarian arteries; of the vesical arteries of the two sides; of the hemorrhoidal branches of the hypogastric artery with those from the inferior mesenteric artery; of the pubic branch of the obturator artery with the vessel of the opposite side, and with the inferior epigastric and medial femoral circumflex arteries; of the circumflex and perforating branches of the arteria profunda femoris with the inferior gluteal artery; of the superior gluteal artery with the posterior branches of the lateral sacral arteries; of the ilio-lumbar with the last lumbar artery; of the middle sacral arteries with the lateral sacral artery; and of the iliac circumflex with the ilio-lumbar and superior gluteal arteries.*

The branches of the hypogastric artery are :

From the Anterior Trunk.

Superior vesical.
Inferior vesical.
Middle hemorrhoidal.
Obturator.

Uterine. } *In the female.*
Vaginal. }

Internal pudendal.
Inferior gluteal.

From the Posterior Trunk.

Ilio-lumbar.
Lateral sacral.
Superior gluteal.

The **superior vesical artery** supplies numerous branches to the upper part of the bladder. From one of these a slender vessel, the *artery to the ductus deferens*,

* For a description of a case in which Owen made a dissection ten years after ligature of the hypogastric artery, see *Med.-Chir. Trans.* vol. xvi.

takes origin and accompanies the ductus deferens in its course to the testis, where it anastomoses with the testicular artery. Other branches supply the ureter. The first part of the superior vesical artery is the proximal, pervious portion of the foetal hypogastric artery.

The **inferior vesical artery** frequently arises in common with the middle hæmorrhoidal artery, and is distributed to the fundus of the bladder, the prostate, the vesiculæ seminales and the lower part of the ureter. The branches to the prostate communicate with the corresponding vessels of the opposite side.

The **middle hæmorrhoidal artery** usually arises with the preceding vessel. It is distributed to the muscular coats of the rectum, anastomosing with the inferior vesical artery and with the superior and inferior hæmorrhoidal arteries. It gives offsets to the vesiculæ seminales and prostate.

FIG. 647.—The arteries of the internal organs of generation of the female seen from behind. (After Hyrtl.)

The **uterine artery** (fig. 647) runs medialwards on the Levator ani and towards the cervix uteri; about 2 cm. from the cervix it crosses above and in front of the ureter, to which it supplies a small branch. Reaching the side of the uterus it ascends in a tortuous manner between the two layers of the broad ligament to the junction of the uterine tube and uterus. It then runs lateralwards towards the hilum of the ovary, and ends by joining with the ovarian artery. It supplies branches to the cervix uteri and others which descend on the vagina; the latter anastomose with branches of the vaginal arteries and form with them two median longitudinal vessels—the *azygos arteries of the vagina*—one of which descends in front of, and the other behind, the vagina. It supplies numerous branches to the body of the uterus, and from its terminal portion twigs are distributed to the uterine tube and the round ligament of the uterus.

The **vaginal artery** usually corresponds to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sends branches to the bulb of the vestibule, the fundus of the bladder, and the contiguous part of the rectum. It assists in forming the azygos arteries of the vagina, and is frequently represented by two or three branches.

The **obturator artery** passes forwards and downwards on the lateral wall of the pelvis, to the upper part of the obturator foramen, and, escaping from the

pelvic cavity through the obturator canal, it divides into an anterior and a posterior branch. In the pelvic cavity this vessel is in relation, laterally, with the obturator fascia which separates it from the Obturator internus muscle; medially, with the ureter, ductus deferens, and peritoneum; the obturator nerve is above it and the obturator vein below it.

Branches.—*Inside the pelvis*, the obturator artery gives off (a) *iliac branches* to the iliac fossa; these supply the bone and the Iliacus, and anastomose with the ilio-lumbar artery; (b) a *vesical branch* which runs medialwards to the bladder; and (c) a *pubic branch* which springs from the vessel just before it leaves the pelvic cavity; this branch ascends upon the back of the os pubis and communicates with the corresponding vessel of the opposite side, and with the pubic branch of the inferior epigastric artery.

Outside the pelvis, the obturator artery divides at the upper margin of the obturator foramen, into an anterior and a posterior branch which encircle the foramen under cover of the Obturator externus.

The *anterior branch* runs forwards on the outer surface of the obturator membrane and then curves downwards along the anterior margin of the foramen. It distributes branches to the Obturator externus, Pectineus, Adductores, and Gracilis, and anastomoses with the posterior branch, and with the medial femoral circumflex artery.

The *posterior branch* follows the posterior margin of the foramen and turns forwards on the inferior ramus of the ischium where it anastomoses with the anterior branch. It gives twigs to the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. It also supplies an articular branch which enters the hip-joint through the acetabular notch, ramifies in the fat at the bottom of the acetabulum and sends a twig along the ligamentum teres to the head of the femur.

FIG. 648.—Variations in the origin and course of obturator artery.

Peculiarities.—In about 28 per cent. of cases the obturator artery springs from the inferior epigastric and descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein, and on the lateral side of the femoral ring (fig. 648A); in such cases it would not be endangered in the operation for strangulated femoral hernia. Occasionally, however, it curves along the free margin of the lacunar ligament (fig. 648B), and if in such circumstances a femoral hernia occurred, the vessel would almost completely encircle the neck of the hernial sac, and would be in great danger of being wounded if an operation were performed for strangulation. It sometimes arises from the main stem or from the posterior trunk of the hypogastric artery, or it may spring from the superior gluteal artery; occasionally it arises from the external iliac artery.

The **internal pudendal artery**, the smaller of the two terminal branches of the anterior trunk of the hypogastric artery, supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **internal pudendal artery in the male** passes downwards and lateralwards to the lower border of the greater sciatic foramen, and emerges from the pelvis between the Piriformis and Coccygeus; it then crosses the ischial spine, and enters the perineum through the lesser sciatic foramen. The artery now crosses the Obturator internus, along the lateral wall of the ischio-rectal fossa, being situated about 4 cm. above the lower margin of the ischial tuberosity. It gradually approaches the margin of the inferior ramus of the ischium and passes forwards between the two layers of the fascia of the urogenital diaphragm; it then runs forwards along the medial margin of the inferior ramus of the os pubis, and at a distance of about 1.25 cm. behind the pubic arcuate ligament it pierces the inferior

fascia of the urogenital diaphragm and divides into the *dorsal* and *deep arteries of the penis*.

Relations.—Within the pelvis, it lies in front of the Piriformis muscle, the sacral plexus of nerves, and the inferior gluteal artery. As it crosses the ischial spine, it is covered by the Gluteus maximus and overlapped by the sacrotuberous ligament. Here the pudendal nerve lies to the medial side, and the nerve to the Obturator internus to the lateral side, of the vessel. In the perineum it lies on the lateral wall of the ischiorectal fossa in a canal (*Alcock's canal*) formed by the splitting of the obturator fascia; it is accompanied by a pair of venæ comitantes and the pudendal nerve.

Branches.—The branches of the internal pudendal artery (figs. 649, 650) are :

Muscular.

Inferior hæmorrhoidal.

Perineal.

Artery of the urethral bulb.

Urethral.

Deep artery of the penis.

Dorsal artery of the penis.

The *muscular branches* consist of two sets : one given off in the pelvis; the other, as the vessel crosses the ischial spine. The first set consists of several small offsets which supply the Levator ani, the Obturator internus, the Piriformis, and the Coccygeus. The branches of the second set are distributed to the Gluteus maximus and external rotator muscles; they anastomose with branches of the inferior gluteal artery.

The *inferior hæmorrhoidal artery* arises from the internal pudendal as it passes above the ischial tuberosity. Piercing the wall of Alcock's canal it divides into two or three branches which cross the ischiorectal fossa, and are distributed to the muscles and integument of the anal region, and send offshoots round the lower edge of the Gluteus maximus to the skin of the buttock. They anastomose with the corresponding vessels of the opposite side, with the superior and middle hæmorrhoidal arteries, and with the perineal artery.

The *perineal artery* arises from the internal pudendal artery, in front of the preceding branches, and turns upwards, crossing either over or under the Transversus perinei superficialis, and runs forwards, parallel to the pubic arch, in the interspace between the Bulbocavernosus and Ischioavernosus, both of which it supplies, and finally divides into several *posterior scrotal branches* which are distributed to the skin and dartos tunic of the scrotum. As it crosses the Transversus perinei superficialis it gives off the *transverse perineal artery* which runs transversely on the cutaneous surface of the muscle, and anastomoses with the corresponding vessel of the opposite side and with the perineal and inferior hæmorrhoidal arteries. It supplies the Transversus perinei superficialis and the structures between the anus and the urethral bulb.

The *artery of the urethral bulb* is a short vessel of relatively large calibre which arises from the internal pudendal artery between the two layers of fascia of the urogenital diaphragm; it passes medialwards, pierces the inferior fascia of the urogenital diaphragm, and gives off branches which ramify in the bulb of the urethra and in the posterior part of the corpus cavernosum urethrae. It supplies a small branch to the bulbo-urethral gland.

The *urethral artery* arises a short distance in front of the artery of the urethral bulb. It runs forwards and medialwards, pierces the inferior fascia of the urogenital diaphragm and enters the corpus cavernosum urethrae, in which it is continued forwards to the glans penis.

The *deep artery of the penis* (artery of the corpus cavernosum penis), one of the terminal branches of the internal pudendal artery, arises from that vessel while it is situated between the two fasciæ of the urogenital diaphragm; it pierces the inferior fascia, and, entering the crus penis obliquely, runs forwards in the centre of the corpus cavernosum penis, to which its branches are distributed.

The *dorsal artery of the penis* ascends between the crus penis and the pubic symphysis, and, piercing the inferior fascia of the urogenital diaphragm, passes between the two layers of the suspensory ligament of the penis, and runs forwards on the dorsum of the penis to the glans, where it divides into two branches, which supply the glans and prepuce. On the penis, it lies between the dorsal nerve and deep dorsal vein, the former being on its lateral side. It supplies the skin and the fibrous sheath of the corpus cavernosum penis, sending branches through the sheath to anastomose with the deep artery of the penis.

The *internal pudendal artery in the female* is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The perineal artery supplies the labia pudendi; the artery of the bulb is distributed to the bulbos vestibuli and the erectile tissue of the vagina; the deep artery of the clitoris supplies the corpus cavernosum clitoridis; the dorsal artery of the clitoris gives branches to the dorsum of that organ, and ends in the glans and prepuce of the clitoris.

FIG. 649.—The superficial branches of the internal pudendal artery.

FIG. 650.—The deeper branches of the internal pudendal artery.

Peculiarities.—The internal pudendal artery is sometimes relatively small, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the *accessory pudendal*, which generally arises from the internal pudendal artery before its exit from the greater sciatic foramen. It passes forwards along the lower part of the bladder and across the side of the prostate to the root of the penis, where it perforates the urogenital diaphragm, and gives off the branches usually derived from the internal pudendal artery. The deficiency most frequently met with is that in which the internal pudendal artery ends as the artery of the urethral bulb, the dorsal and deep arteries of the penis being derived from the accessory pudendal artery. The internal pudendal artery may also end as the perineal, the artery of the urethral bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudendal artery is derived from one of the other branches of the hypogastric artery, most frequently the inferior vesical or the obturator.

The **inferior gluteal artery** (sciatic artery) (fig. 651), the larger of the two terminal branches of the anterior trunk of the hypogastric artery, is distributed chiefly to the buttock and back of the thigh. It passes down on the sacral plexus of nerves and the Piriformis, behind the internal pudendal artery, to the lower part of the greater sciatic foramen, through which it escapes from the pelvis between the Piriformis and Coccygeus. It then descends in the interval between the greater trochanter of the femur and the tuberosity of the ischium, accompanied by the sciatic and posterior femoral cutaneous nerves, and covered by the Glutæus maximus; it is continued down the back of the thigh, supplying the skin, and anastomosing with branches of the perforating arteries.

Inside the pelvis it distributes (a) branches to the Piriformis, Coccygeus, and Levator ani; (b) branches which supply the fat around the rectum, and occasionally take the place of the middle hæmorrhoidal artery; and (c) vesical branches to the fundus of the bladder, vesiculæ seminales, and prostate.

Outside the pelvis it gives off the following branches:

Muscular branches supply the Glutæus maximus, the external rotators of the thigh, and the muscles attached to the tuberosity of the ischium; they anastomose with the superior gluteal, internal pudendal, obturator and medial femoral circumflex arteries.

Coccygeal branches run medialwards, pierce the sacrotuberous ligament, and supply the Glutæus maximus and the structures on the back of the coccyx.

The *arteria comitans nervi ischiadici*, a long slender vessel, accompanies the sciatic nerve for a short distance; it then penetrates it, and runs in its substance to the lower part of the thigh.

An *anastomotic branch* is directed obliquely downwards across the external rotator muscles of the thigh, and assists in forming the so-called *crucial anastomosis* by joining with the first perforating and the medial and lateral femoral circumflex arteries.

An *articular branch*, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

Cutaneous branches are distributed to the skin of the buttock and back of the thigh.

The **iliolumbar artery**, a branch of the posterior trunk of the hypogastric artery turns upwards behind the obturator nerve and the external iliac vessels, to the medial border of the Psoas major, behind which it divides into a lumbar and an iliac branch.

The *lumbar branch* supplies the Psoas major and Quadratus lumborum, anastomoses with the fourth lumbar artery, and sends a small *spinal branch* through the intervertebral foramen between the fifth lumbar vertebra and the base of the sacrum, into the vertebral canal to supply the cauda equina.

The *iliac branch* supplies the Iliacus; some offsets run between the muscle and the bone and anastomose with the iliac branches of the obturator artery; one of these enters an oblique canal to supply the bone, while others run along the crest of the ilium, distributing branches to the gluteal and abdominal muscles, and anastomosing in their course with the superior gluteal, iliac circumflex, and lateral femoral circumflex arteries.

The **lateral sacral arteries** (fig. 646) arise from the posterior division of the hypogastric artery; there are usually two, a superior and an inferior. The *superior* and larger passes medialwards, and, after anastomosing with branches from the middle sacral artery, enters the first or second anterior sacral foramen, supplies branches to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, is distributed to the skin and muscles on the dorsum of the sacrum, anastomosing with the superior gluteal. The *inferior* runs obliquely across the front of the Piriformis and the sacral nerves, to the medial side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the middle sacral artery and the opposite lateral sacral arteries.

Branches of it enter the anterior sacral foramina, and, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the glutæal arteries.

FIG. 651.—The arteries of the glutæal and posterior femoral regions.

The **superior glutæal artery** (fig. 651) is the largest branch of the hypogastric artery, and appears to be the continuation of the posterior division of that vessel. It is a short artery which runs backwards between the lumbosacral trunk and the first sacral nerve, and, passing out of the pelvis above the upper border of the Piriformis, immediately divides into a *superficial* and a *deep branch*. Within the pelvis it gives off a few branches to the Iliacus, Piriformis, and Obturator internus, and just previous to quitting the pelvis, a nutrient artery to the ilium.

The *superficial branch* enters the deep surface of the Glutæus maximus, and divides into numerous branches; some of these supply the muscle and anastomose

with the inferior gluteal, while others perforate the tendinous origin of the muscle, supply the skin covering the posterior surface of the sacrum, and anastomose with the posterior branches of the lateral sacral arteries.

The *deep branch* lies under the Glutæus medius and almost immediately subdivides into two. Of these, the *superior division* passes along the upper border of the Glutæus minimus to the anterior superior spine of the ilium, anastomosing with the deep iliac circumflex artery and the ascending branch of the lateral femoral circumflex artery. The *inferior division* crosses the Glutæus minimus obliquely to the greater trochanter, distributes branches to the Glutæi, and anastomoses with the lateral femoral circumflex artery; some branches pierce the Glutæus minimus and supply the hip-joint.

Applied Anatomy.—Either of the gluteal arteries may require to be ligatured for a wound, or for aneurysm, which is generally traumatic. The *superior gluteal artery* is ligatured by turning the patient two-thirds over on to his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the greater trochanter. This exposes the Glutæus maximus, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the Glutæus medius and Piriformis are now to be separated from each other, and the artery will be exposed emerging from the greater sciatic foramen. In ligature of the *inferior gluteal artery*, the incision should be made parallel with that for ligature of the superior gluteal but 4 cm. lower down. After the fibres of the Glutæus maximus have been separated, the vessel is to be sought at the lower border of the Piriformis: the sciatic nerve, which lies just above it, forms the chief guide to the artery.

EXTERNAL ILIAC ARTERY (fig. 646)

The **external iliac artery** is larger than the hypogastric artery, and runs obliquely downwards and lateralwards, along the medial border of the Psoas major, from the bifurcation of the common iliac artery to a point beneath the inguinal ligament, midway between the anterior superior iliac spine and the symphysis pubis, where it enters the thigh and becomes the femoral artery.

Relations.—*In front and medially* the artery is in relation with the peritoneum and subperitoneal areolar tissue which separate the right artery from the termination of the ileum and frequently the vermiform process, and the left artery from the sigmoid colon and some coils of the small intestine. The beginning of the artery may be crossed by the ureter; in the female it is crossed by the ovarian vessels. The testicular vessels lie for some distance upon it near its termination, and it is crossed in this situation by the external spermatic branch of the genitofemoral nerve, the deep iliac circumflex vein, the ductus deferens in the male, and the round ligament of the uterus in the female. *Posteriorly*, it is separated from the medial border of the Psoas major by the iliac fascia. The external iliac vein lies partly behind the upper part of the artery, but is on the medial side of its lower part. *Lateral* to it is the Psoas major, from which it is separated by the iliac fascia. Numerous lymphatic vessels and lymph-glands lie on the front and sides of the vessel.

Applied Anatomy.—The application of a ligature to the external iliac may be required in cases of iliofemoral aneurysm (i.e. at the point where the artery passes beneath the inguinal ligament), or for an aneurysm or a wound of the femoral artery itself. The vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the hypogastric artery, and near its lower end, which should also be avoided on account of the proximity of its inferior epigastric and deep iliac circumflex branches. The operation may be performed by opening the abdomen and incising the peritoneum over the artery (*transperitoneal*); or by an incision in the iliac region, dividing all the structures down to the peritoneum, which is then separated unopened from the iliac fossa until the artery is reached (*retroperitoneal*).

The transperitoneal ligature is essentially similar to that described on p. 643 for the common iliac artery. The advantages of this operation are: (1) if it be found necessary, the common iliac artery can be ligatured instead of the external iliac without extension or modification of the incision; and (2) the vessel can be ligatured without in any way interfering with the sac of an aneurysm.

The retroperitoneal ligature may be performed by an incision above and parallel to the lateral half of the inguinal ligament. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised towards the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the medial border of the Psoas major. The

external iliac vein, generally found on the medial side of the artery, must be cautiously separated from it, and the aneurysm needle introduced on the medial side, between the artery and vein.

Collateral Circulation.—The principal anastomoses by which the collateral circulation is established, after ligature of the external iliac artery, are: the iliolumbar with the iliac circumflex arteries; the superior gluteal with the lateral femoral circumflex artery; the obturator with the medial femoral circumflex artery; the inferior gluteal with the circumflex and first perforating branches of the arteria profunda femoris; and the internal pudendal with the external pudendal artery. When the obturator artery arises from the inferior epigastric artery, it is supplied with blood by branches from either the hypogastric, the lateral sacral, or the internal pudendal arteries. The inferior epigastric artery receives its supply from the internal mammary and lower intercostal arteries, and from the hypogastric artery by the anastomoses of its branches with the obturator artery.*

Branches.—Besides supplying several small branches to the Psoas major and the neighbouring lymph-glands, the external iliac artery gives off the inferior epigastric and deep circumflex iliac branches.

The **inferior epigastric artery** (deep epigastric artery) (fig. 651) arises from the external iliac artery, immediately above the inguinal ligament. It curves forwards in the subperitoneal tissue, and then ascends obliquely along the medial margin of the abdominal inguinal ring; continuing its upward course, it pierces the transversalis fascia, passes in front of the linea semicircularis, and ascends between the Rectus abdominis and the posterior lamella of its sheath. It finally divides into numerous branches, which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary artery and with the lower intercostal arteries. As the inferior epigastric artery passes obliquely upwards from its origin it lies along the lower and medial margins of the abdominal inguinal ring, and behind the commencement of the spermatic cord. In the male the ductus deferens, and in the female the round ligament of the uterus, winds round the lateral and posterior aspects of the artery. It supplies the following branches:

The **external spermatic artery** (cremasteric artery) accompanies the spermatic cord, supplies the Cremaster and other coverings of the cord, and anastomoses with the testicular artery. In the female the external spermatic artery is very small and accompanies the round ligament of the uterus.

A **pubic branch** descends along the medial margin of the femoral ring to the back of the os pubis, and there anastomoses with the pubic branch of the obturator artery.

Branches are distributed to the abdominal muscles and peritoneum, and anastomose with the iliac circumflex and lumbar arteries.

Cutaneous branches perforate the tendon of the Obliquus externus, supply the skin and anastomose with branches of the superficial epigastric artery.

Peculiarities.—The origin of the inferior epigastric artery may take place from any part of the external iliac artery between the inguinal ligament and a point 6 cm. above it; or it may arise below this ligament, from the femoral artery. It frequently springs from the external iliac artery, by a common trunk with the obturator artery. Sometimes it arises from the obturator artery, the latter vessel being furnished by the hypogastric artery, or it may be formed of two branches, one derived from the external iliac artery, the other from the hypogastric artery.

Applied Anatomy.—The inferior epigastric artery has important surgical relations, and is one of the principal means, through its anastomosis with the internal mammary, of establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the abdominal inguinal ring, and is therefore *medial* to an oblique inguinal hernia, but *lateral* to a direct inguinal hernia, as these emerge from the abdomen. It forms the lateral boundary of Hesselbach's triangle, and is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The ductus deferens hooks round its lateral side.

The **deep iliac circumflex artery** arises from the lateral side of the external iliac nearly opposite the inferior epigastric artery. It ascends obliquely behind the inguinal ligament, in a sheath formed by the junction of the transversalis and iliac fasciæ, to the anterior superior iliac spine, where it anastomoses with the ascending branch of the lateral femoral circumflex artery. It then pierces the transversalis fascia and passes along the inner lip of the crest of the ilium to about its middle, where it perforates the Transversus abdominis and runs backwards

* Sir Astley Cooper describes in vol. i. of the *Guy's Hospital Reports* the dissection of a limb eighteen years after successful ligature of the external iliac artery.

between that muscle and the *Obliquus internus*, to anastomose with the iliolumbar and superior gluteal arteries. Opposite the anterior superior iliac spine it gives off a large branch, which ascends between the *Obliquus internus* and *Transversus* muscles, supplying them, and anastomosing with the lumbar and inferior epigastric arteries.

ARTERIES OF THE LOWER EXTREMITY

The chief artery of the lower extremity is a direct continuation of the external iliac. It extends from the level of the inguinal ligament to the lower border of the *Popliteus*, where it divides into the anterior and posterior tibial arteries. Its upper part is named the femoral artery, its lower the popliteal artery.

FEMORAL ARTERY (figs. 655, 656)

The **femoral artery** begins immediately behind the inguinal ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and passes down the front and medial side of the thigh. It ends at the

FIG. 652. -Femoral sheath laid open to show its three compartments.

junction of the middle and lower thirds of the thigh where it passes through an opening in the *Adductor magnus* to become the popliteal artery. The first 3 cm. or 4 cm. of the vessel are enclosed, together with the femoral vein, in the *femoral sheath*. The upper part of the femoral artery is contained in the *femoral triangle* (Scarpa's triangle), the lower part in the *adductor canal* (Hunter's canal).

The **femoral sheath** (figs. 652, 653) is formed by a prolongation downwards, behind the inguinal ligament, of the fasciæ which line the abdomen, the

transversalis fascia being continued down in front of the femoral vessels and the iliopectineal fascia behind them. The sheath assumes the form of a short funnel, the wide end of which is directed upwards, while the lower, narrow end fuses with the fascial investment of the vessels, about 3 or 4 cm. below the inguinal ligament. The lateral wall of the sheath is vertical and is perforated by the lumbo-inguinal nerve; the medial wall is directed obliquely downwards and lateralwards, and is pierced by the great saphenous vein and by some lymphatic vessels. The sheath is divided by two vertical partitions which stretch between its anterior and posterior walls. The lateral compartment contains the femoral artery, and the intermediate the femoral vein; the medial and smallest compartment is named the *femoral canal*, and contains some lymphatic vessels and a lymph-gland, imbedded in a small amount of areolar

FIG. 653.—Structures passing behind the inguinal ligament.

tissue. The femoral canal is conical and measures about 1.25 cm. in length; its base, directed upwards and named the *femoral ring*, is oval in form, its long diameter being directed transversely and measuring about 1.25 cm. The femoral ring (figs. 653, 654) is bounded in front by the inguinal ligament, behind by the Pectineus covered by its fascia, medially by the crescentic base of the lacunar ligament, and laterally by the femoral vein. The spermatic cord in the male, and the round ligament of the uterus in the female, lie immediately above the anterior margin of the ring, while the inferior epigastric vessels are close to its upper and lateral angle. The femoral ring is closed by a somewhat condensed portion of the extraperitoneal connective tissue, named the *septum femorale* (crural septum), the abdominal surface of which supports a small lymph-gland and is covered by the parietal layer of the peritoneum. The septum femorale is pierced by numerous lymphatic vessels passing from the deep inguinal to the external iliac lymph-glands, and the parietal peritoneum immediately above it presents a slight depression named the *femoral fossa*.

The *femoral triangle* (triangle of Scarpa) (fig. 655), corresponds to the depression seen immediately below the fold of the groin. Its apex is directed downwards, and the sides are formed laterally by the medial margin of the Sartorius, medially by the medial margin of the Adductor longus, above by the inguinal ligament. The floor of the triangle is formed from its lateral to its medial side by the Iliacus, Psoas major, Pectineus, and Adductor longus;

and it is divided into two nearly equal parts by the femoral vessels, which extend from near the middle of its base to its apex. On the lateral side of the femoral artery is the femoral nerve dividing into its branches. Besides the vessels and nerves, this triangle contains some fat and lymphatics.

The **adductor canal** (Hunter's canal) is an aponeurotic tunnel in the middle third of the thigh, extending from the apex of the femoral triangle to the opening in the Adductor magnus. It is bounded, in front and laterally, by the Vastus medialis; behind, by the Adductor longus and Adductor magnus; and is covered in by a strong aponeurosis which extends from these muscles, across the femoral vessels, to the Vastus medialis; lying on the aponeurosis is the Sartorius muscle. The canal contains the femoral artery and vein, the saphenous nerve, and the nerve to the Vastus medialis.

FIG. 654.—The relations of the femoral and abdominal inguinal ring seen from within the abdomen. Right side.

Relations of the femoral artery.—In the *femoral triangle* (fig. 655) the artery is covered by the skin and superficial fascia, the superficial subinguinal lymph-glands, the superficial iliac circumflex vein, the superficial layer of the fascia lata, and the anterior part of the femoral sheath. The lumbo-inguinal nerve courses for a short distance within the lateral compartment of the femoral sheath, and lies at first in front of and then lateral to the artery. Near the apex of the femoral triangle the medial branch of the anterior femoral cutaneous nerve crosses the artery from its lateral to its medial side.

Behind the artery are the posterior part of the femoral sheath, the pectineal fascia, the tendon of the Psoas major, the Pectineus and the Adductor longus. The artery is separated from the capsule of the hip-joint by the tendon of the Psoas major, from the Pectineus by the femoral vein and profunda vessels, and from the Adductor longus by the femoral vein. The nerve to the Pectineus passes medialwards behind the artery. On the *lateral* side of the artery, is the femoral nerve. The femoral vein is medial to the artery in the upper part of the femoral triangle, and posterior to the artery in the lower part.

In the *adductor canal* (fig. 656) the femoral artery is more deeply situated, being covered by the skin, the superficial and deep fasciæ, the Sartorius, and the fibrous roof of the canal; the saphenous nerve crosses it anteriorly from its lateral to its medial side. Behind the artery are the Adductor longus and Adductor magnus; in front and lateral to it is the Vastus medialis. The femoral vein lies posterior to the upper, and lateral to the lower, part of the artery.

Peculiarities.—Several cases are recorded where the femoral artery divided, below the origin of the profunda, into two trunks, which reunited near the opening in the Adductor magnus. A few cases have been reported where the femoral artery was absent, its place being supplied by the inferior gluteal artery which accompanied the sciatic nerve to the popliteal fossa; in these cases the external iliac artery was small, and terminated as the arteria profunda femoris. The femoral vein is occasionally placed along the medial side of the artery throughout the entire extent of the femoral triangle; or it may be duplicated so that a large vein is placed on either side of the artery for a greater or lesser distance.

FIG. 655. —The left femoral triangle.

Applied Anatomy.—Compression of the femoral artery, which is constantly requisite in amputations and other operations on the lower limb, is most effectually made immediately below the inguinal ligament. In this situation the artery is superficial, and is separated from the superior ramus of the os pubis by the Psoas major; here digital compression will effectually control the circulation through it. The vessel may also be controlled in the middle third of the thigh by a tourniquet, which presses the vessel against the medial side of the femur.

The superficial position of the femoral artery in the femoral triangle renders it particularly liable to be injured in wounds, stabs, or gunshot injuries in the groin. On account of the close relationship between the femoral artery and vein, the latter vessel is also liable to be wounded in these injuries. In such cases, the artery having been compressed as it crosses the ramus of the os pubis, the skin wound should be enlarged and the wound in the vessel sought for, and a ligature applied above and below the bleeding point.

Ligature of the femoral artery may be required in cases of wound or aneurysm of the femoral or popliteal arteries or of the arteries of the leg; and the vessel may be exposed and tied in any part of its course. The most favourable situation is at the apex of the femoral triangle. An incision 7 cm. long should be made in the course of the vessel, the

patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outwards. A large vein is frequently met with, passing in the course of the artery to join the great saphenous vein, and must be avoided. The fascia lata having been cautiously divided, and the Sartorius displayed, that muscle must be drawn lateralwards in order to expose fully the sheath of the vessels. The finger having been introduced into the wound, and the pulsation of the artery felt, the sheath is opened on the lateral side of the vessel to a sufficient extent to allow of the introduction of the aneurysm needle. In this part of the operation the saphenous nerve and the nerve to the Vastus medialis, which are in close relation with the sheath, should be avoided. The aneurysm needle must be kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course, and is very closely bound up with it.

To expose the artery in the adductor canal, an incision 7 cm. in length should be made a finger's breadth medial to the line of the artery, the centre of the incision being in the middle of the thigh—i.e. midway between the groin and the knee. The fascia lata having been divided, and the lateral border of the Sartorius exposed, this muscle should be drawn medialwards, when the strong fascia which is stretched across from the Adductors to the Vastus medialis will be observed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurysm needle between it and the vein, from the lateral to the medial side of the artery. In this situation the femoral vein lies lateral to, and the saphenous nerve in front of the artery.

Collateral Circulation.—After ligation of the femoral artery, the main channels for carrying on the circulation are the following anastomoses:—(1) the superior and inferior gluteal branches of the hypogastric artery with the medial and lateral femoral circumflex and first perforating branches of the arteria profunda femoris; (2) the obturator branch of the hypogastric artery with the medial femoral circumflex of the arteria profunda femoris; (3) the internal pudendal branch of the hypogastric artery with the superficial and deep external pudendal branches of the femoral artery; (4) the deep iliac circumflex branch of the external iliac artery with the lateral femoral circumflex branch of the arteria profunda femoris and the superficial iliac circumflex branch of the femoral artery; and (5) the inferior gluteal branch of the hypogastric artery with the perforating branches of the arteria profunda femoris.

Branches.—The branches of the femoral artery are :

- | | |
|-----------------------------------|----------------------------|
| 1. Superficial epigastric. | 4. Deep external pudendal. |
| 2. Superficial iliac circumflex. | 5. Muscular. |
| 3. Superficial external pudendal. | 6. Profunda femoris. |
| 7. Highest genicular. | |

1. The **superficial epigastric artery** arises from the front of the femoral artery about 1 cm. below the inguinal ligament, and, piercing the femoral sheath and the fascia cribrosa, ascends in front of the inguinal ligament, and between the two layers of the superficial fascia of the abdominal wall nearly as far as the umbilicus. It distributes branches to the superficial subinguinal lymph-glands, the superficial fascia, and the skin; it anastomoses with branches of the inferior epigastric artery, and with its fellow of the opposite side.

2. The **superficial iliac circumflex artery**, the smallest of the superficial branches, arises close to the preceding, and, piercing the fascia lata, runs lateralwards, parallel with the inguinal ligament, as far as the crest of the ilium; it gives branches to the skin, superficial fascia, and superficial subinguinal lymph-glands, and anastomoses with the deep iliac circumflex, the superior gluteal and the lateral femoral circumflex arteries.

3. The **superficial external pudendal artery** arises from the medial side of the femoral artery, close to the preceding vessels, and, after piercing the femoral sheath and fascia cribrosa, courses medialwards, across the spermatic cord (or round ligament of the uterus in the female), to be distributed to the skin on the lower part of the abdomen, the penis and scrotum in the male, and the labium majus in the female, anastomosing with branches of the internal pudendal artery.

4. The **deep external pudendal artery** passes medialwards across the Pectineus and the Adductor longus; it is covered by the fascia lata, which it pierces at the medial side of the thigh, and is distributed, in the male, to the skin of the scrotum and perinæum, in the female to the labium majus; its branches anastomose with the scrotal (or labial) branches of the perinæal artery.

5. **Muscular branches** are supplied by the femoral artery to the Sartorius, Vastus medialis, and Adductores.

6. The *arteria profunda femoris* (fig. 656) is a large vessel arising from the lateral side of the femoral artery, about 3.5 cm. below the inguinal ligament. At first it lies lateral to the femoral artery, and then runs behind it and the femoral vein to the medial side of the femur; it is continued downwards behind the Adductor longus, and ends at the lower third of the thigh in a small branch which pierces the Adductor magnus and anastomoses with the superior muscular branches of the popliteal artery. The terminal part of the profunda is sometimes named the *fourth perforating artery*.

Relations.—*Behind* it, from above downwards, are the Iliacus, Pectineus, Adductor brevis, and Adductor magnus. *In front*, it is separated from the femoral artery by the femoral and profunda veins above, and by the Adductor longus below. *Laterally*, the origin of the Vastus medialis intervenes between it and the femur.

Peculiarities.—This vessel sometimes arises from the medial side, more rarely from the back of the femoral artery. In most cases it arises between 2.25 cm. and 5 cm. below the inguinal ligament; in a few cases the distance is less than 2.25 cm.; more rarely it arises opposite the ligament. Occasionally the distance between the origin of the vessel and the inguinal ligament exceeds 5 cm.

The *arteria profunda femoris* gives off the following branches :

Lateral femoral circumflex.	Perforating.
Medial femoral circumflex.	Muscular.

The **lateral femoral circumflex artery** (external circumflex artery) arises from the lateral side of the profunda, passes lateralwards between the divisions of the femoral nerve and behind the Sartorius and Rectus femoris, and divides into ascending, transverse, and descending branches.

The *ascending branch* passes upwards beneath the Tensor fasciæ latæ to the lateral part of the hip, and anastomoses with the terminal branches of the superior gluteal and deep iliac circumflex arteries.

The *descending branch* runs downwards, behind the Rectus femoris, upon the Vastus lateralis, to which it gives offsets; one long branch descends in the muscle as far as the knee, and anastomoses with the superior lateral genicular branch of the popliteal artery. It is accompanied by the nerve to the Vastus lateralis.

The *transverse branch*, the smallest, passes lateralwards over the Vastus intermedius, pierces the Vastus lateralis, and winds round the femur, just below the greater trochanter, anastomosing on the back of the thigh with the medial femoral circumflex, inferior gluteal, and first perforating arteries.

The **medial femoral circumflex artery** (internal circumflex artery) usually arises from the posteromedial aspect of the profunda, but may spring from the femoral. It winds round the medial side of the femur, passing first between the Pectineus and Psoas major, and then between the Obturator externus and Adductor brevis. At the upper border of the Adductor brevis it gives off two branches; one is distributed to the Adductores, the Gracilis, and Obturator externus, and anastomoses with the obturator artery; the other descends behind the Adductor brevis to supply it and the Adductor magnus; the continuation of the vessel passes backwards and divides into superficial, deep, and acetabular branches. The *superficial branch* appears between the Quadratus femoris and upper border of the Adductor magnus, and anastomoses with the inferior gluteal, lateral femoral circumflex, and first perforating arteries (*crucial anastomosis*). The *deep branch* runs obliquely upwards upon the tendon of the Obturator externus and in front of the Quadratus femoris towards the trochanteric fossa, where it anastomoses with twigs from the gluteal arteries. The *acetabular branch* arises opposite the acetabular notch and enters the hip-joint beneath the transverse acetabular ligament in company with an articular branch from the obturator artery; it supplies the fat in the bottom of the acetabulum, and is continued along the round ligament to the head of the femur.

The **perforating arteries** (fig. 651), usually three in number, are so named because they perforate the insertion of the Adductor magnus to reach the back of the thigh. They pass backwards close to the linea aspera of the femur under cover of small tendinous arches in the muscle. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The *first perforating artery* passes backwards between the Pectineus and Adductor brevis (sometimes it perforates the latter muscle); it then pierces the Adductor magnus close to the linea aspera. It gives branches to the Adductor brevis,

FIG. 656.—The right femoral artery.

Adductor magnus, Biceps femoris, and Glutæus maximus, and anastomoses with the inferior glutæal, medial and lateral femoral circumflex, and second perforating arteries.

The *second perforating artery*, larger than the first, but frequently arising in common with it, pierces the tendons of the Adductor brevis and Adductor magnus, and divides into ascending and descending branches which supply the posterior femoral muscles, anastomosing with the first and third perforating. The *nutrient*

artery of the femur is usually given off from this artery ; when two nutrient arteries exist, they usually spring from the first and third perforating vessels.

The *third perforating artery* is given off below the Adductor brevis ; it pierces the Adductor magnus and divides into branches which supply the posterior femoral muscles, and anastomose above with the higher perforating arteries, and below with the termination of the profunda and the muscular branches of the popliteal. The nutrient artery of the femur may arise from this branch.

The termination of the profunda artery, already described, is sometimes called the *fourth perforating artery*.

Numerous **muscular branches** arise from the profunda ; some of these end in the Adductores, others pierce the Adductor magnus, give branches to the hamstrings, and anastomose with the medial femoral circumflex artery and with the superior muscular branches of the popliteal.

7. The **highest genicular artery** (*arteria anastomotica magna*) (fig. 656) arises from the femoral just before it passes through the opening in the tendon of the Adductor magnus, and immediately divides into a saphenous and a musculo-articular branch.

The *saphenous branch* pierces the aponeurotic covering of the adductor canal, and accompanies the saphenous nerve to the medial side of the knee. It passes between the Sartorius and Gracilis, and is distributed to the skin of the upper and medial part of the leg, anastomosing with the medial inferior genicular artery.

The *musculo-articular branch* descends in the substance of the Vastus medialis, and in front of the tendon of the Adductor magnus, to the medial side of the knee, where it anastomoses with the medial superior genicular and anterior recurrent tibial arteries. A branch from this vessel crosses above the patellar surface of the femur, forming an anastomotic arch with the lateral superior genicular artery, and supplying branches to the knee-joint.

POPLITEAL FOSSA (fig. 657)

Boundaries.—The popliteal fossa or space is a lozenge-shaped space, at the back of the knee-joint. Laterally it is bounded by the Biceps femoris above, and by the Plantaris and the lateral head of the Gastrocnemius below ; medially it is limited by the Semitendinosus and Semimembranosus above, and by the medial head of the Gastrocnemius below. The floor is formed by the popliteal surface of the femur, the oblique popliteal ligament of the knee-joint, the back of the upper end of the tibia, and the fascia covering the Popliteus ; the fossa is covered in by the fascia lata.

Contents.—The popliteal fossa contains the popliteal vessels, the tibial and the common peroneal nerves, the termination of the small saphenous vein, the lower part of the posterior femoral cutaneous nerve, the articular branch from the obturator nerve, a few small lymph-glands, and a considerable quantity of fat. The tibial nerve descends through the middle of the fossa, lying under the deep fascia, and crossing the vessels posteriorly from the lateral to the medial side. The common peroneal nerve descends on the lateral side of the upper part of the fossa, close to the tendon of the Biceps femoris. On the floor of the fossa are the popliteal vessels, the vein being superficial to the artery and united to it by dense areolar tissue ; the vein is a thick-walled vessel, and lies at first lateral to the artery, and then crosses it posteriorly to gain its medial side below ; sometimes it is double, the artery lying between the two veins, which are usually connected by short transverse branches. The articular branch from the obturator nerve descends upon the artery to the knee-joint. The popliteal lymph-glands, six or seven in number, are imbedded in the fat ; one lies beneath the popliteal fascia near the termination of the external saphenous vein, another between the popliteal artery and the back of the knee-joint, while the others are placed at the sides of the popliteal vessels.

POPLITEAL ARTERY (fig. 657)

The **popliteal artery** is the continuation of the femoral artery, and courses through the popliteal fossa. It extends from the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, downwards and laterally to the intercondyloid fossa of the femur, and then vertically downwards to the lower border of the Popliteus, where it divides into *anterior* and *posterior tibial arteries*.

Relations.—In *front* of the artery, from above downwards, are the popliteal surface of the femur (separated from the vessel by some fat), the back of the knee-joint, and the fascia covering the Popliteus. *Behind*, it is overlapped by the Semimembranosus above, and is covered by the Gastrocnemius and Plantaris below. In the middle part of its course the artery is separated from the skin and fasciæ by a quantity of fat, and is crossed from the lateral to the medial side by the tibial nerve and the popliteal vein, the vein being between the nerve and the artery and closely adherent to the latter. On its *lateral side*, above, are the Biceps femoris, the tibial nerve, the popliteal vein, and the lateral condyle of the femur; below, the Plantaris and the lateral head of the Gastrocnemius. On its *medial side*, above, are the Semimembranosus and the medial condyle of the femur; below, the tibial nerve, the popliteal vein, and the medial head of the Gastrocnemius. The relations of the popliteal lymph-glands to the artery are described on the previous page.

Peculiarities.—Occasionally the popliteal artery divides into its terminal branches opposite the knee-joint; when this occurs the anterior tibial artery usually descends in front of the Popliteus. The popliteal artery sometimes divides into the anterior tibial and peroneal arteries, the posterior tibial artery being wanting, or rudimentary; occasionally it divides into three branches, the anterior and posterior tibial, and peroneal arteries.

Applied Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee, or by hyperextension of the knee. It may also be lacerated by fracture of the lower part of the femur, or by anteroposterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded in performing Macewen's operation of osteotomy of the lower end of the femur for genu valgum. It is more frequently the seat of aneurysm than any other artery except the thoracic aorta. No doubt this is due in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries. When the knee is acutely flexed, the popliteal artery becomes bent on itself to such an extent as entirely to arrest the circulation through it.

Ligature of the popliteal artery is required in cases of wound of the vessel, but for aneurysm it is preferable to tie the femoral. The popliteal may be tied in the upper or lower part of its course; in the middle of the popliteal fossa the operation is attended with considerable difficulty, from the great depth of the vessel, and from the extreme degree of tension of the lateral and medial boundaries of the fossa.

In order to expose the upper part of the vessel, the patient should be placed in the supine position, with the knee flexed and the thigh abducted and rotated outwards so that it rests on its lateral surface; an incision 7 cm. or 8 cm. in length, beginning at the junction of the middle with the lower third of the thigh, is to be made parallel to and immediately behind the tendon of the Adductor magnus, and the skin, superficial and deep fasciæ divided. The tendon of the muscle is thus exposed, and is to be drawn forwards, and the hamstring tendons backwards. A quantity of fatty tissue will now be opened up, in which the artery will be felt pulsating. This tissue is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the lateral side of the artery. The sheath is to be opened, and the aneurysm needle passed from before backwards, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid in the superficial incision is the great saphenous vein.

To expose the vessel in the lower part of its course, where it lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the skin in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the small saphenous vein and the medial sural cutaneous nerve. After dividing the deep fascia, and separating some dense cellular tissue, the artery, vein, and nerve will be exposed between the two heads of the Gastrocnemius. Some muscular branches of the artery should be avoided if possible, or, if divided, tied immediately. The leg being now flexed,

in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn medialwards and the vein lateralwards, and the aneurysm needle passed between the artery and vein from the lateral to the medial side.

FIG. 657.—The popliteal, posterior tibial, and peroneal arteries.

Branches.—The branches of the popliteal artery are :

Cutaneous.

Muscular

Genicular

{ Superior.
 { Sural.
 { Medial superior.
 { Lateral superior.
 { Middle.
 { Medial inferior.
 { Lateral inferior.

The **cutaneous branches** arise either from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius, and, piercing the deep fascia, are distributed to the skin of the back of the leg; one usually accompanies the small saphenous vein.

The **superior muscular branches**, two or three in number, arise from the upper part of the artery, and pass to the Adductor magnus and the hamstring muscles, anastomosing with the terminal part of the arteria profunda femoris.

The **sural arteries** are two large branches which arise opposite the knee-joint and are distributed to the Gastrocnemius, Soleus, and Plantaris.

The **superior genicular arteries** (superior articular arteries) (figs. 657, 658), two in number, arise one on either side of the popliteal artery, and wind round the femur immediately above its condyles to the front of the knee-joint. The **medial superior genicular artery** runs in front of the Semimembranosus and Semitendinosus, above the medial head of the Gastrocnemius, and passes beneath the tendon of the Adductor magnus. It divides into two branches, one of which supplies the Vastus medialis and anastomoses with the highest genicular and medial inferior genicular arteries; the other ramifies close to the surface of the femur, and anastomoses with the lateral superior genicular artery. The size of the medial superior genicular artery varies inversely with that of the highest genicular. The **lateral superior genicular artery** passes beneath the tendon of the Biceps femoris, and divides into a superficial and a deep branch; the superficial branch supplies the Vastus lateralis, and anastomoses with the descending branch of the lateral femoral circumflex artery and with the lateral inferior genicular artery; the deep branch anastomoses with the medial inferior

genicular artery, and forms an arch across the front of the bone with the highest genicular artery.

The **middle genicular artery** (azygos articular artery), a small branch, arises from the popliteal artery opposite the back of the knee-joint; it pierces the oblique popliteal ligament, and supplies the cruciate ligaments and the synovial stratum of the articular capsule.

The **inferior genicular arteries** (inferior articular arteries) (figs. 657, 658), two in number, arise from the popliteal artery beneath the Gastrocnemius. The **medial inferior genicular artery** descends along the upper margin of the Popliteus, to which it gives branches; it then passes below the medial condyle of the tibia and beneath

FIG. 658.—Anastomosis around the knee-joint.

the tibial collateral ligament; at the anterior border of this ligament it ascends to the front and medial side of the joint, supplies the joint and the upper end of the tibia and anastomoses with the lateral inferior and medial superior genicular arteries. The **lateral inferior genicular artery** runs lateralwards above the head of the fibula to the front of the knee-joint, passing in its course beneath the lateral head of the Gastrocnemius, the fibular collateral ligament, and the tendon of the Biceps femoris. It divides into branches which anastomose with the medial inferior genicular, lateral superior genicular, and anterior recurrent tibial arteries.

The **anastomosis around the knee-joint** (fig. 658).—Around and above the patella, and on the contiguous ends of the femur and tibia, is an intricate arterial anastomosis forming a superficial and a deep network. The **superficial network** is situated between the fascia and skin round about the patella, and forms three well-defined arches; one above the patella in the loose connective tissue over the Quadriceps femoris, and two below the patella in the fat behind the ligamentum patellæ. The **deep network** lies on the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offsets into the interior of the joint. The arteries which form the anastomosis are the two medial and the two lateral genicular branches of the popliteal, the highest genicular, the descending branch of

FIG. 659.—Anterior tibial and dorsalis pedis arteries.

the lateral femoral circumflex, the fibular, and the anterior recurrent tibial.

ANTERIOR TIBIAL ARTERY (fig. 659)

The anterior tibial artery begins at the bifurcation of the popliteal artery, at the lower border of the Popliteus, passes forwards between the two heads of the Tibialis posterior and through the upper part of the crural interosseous membrane, to the front of the leg: it here lies close to the medial side of the neck of the fibula. It descends on the anterior surface of the crural interosseous membrane, gradually approaching the tibia: at the lower part of the leg it lies on this bone, and then on the front of the ankle-joint midway between the two malleoli, where it becomes the *dorsalis pedis* artery.

Relations.—In the upper two-thirds of its extent, the anterior tibial artery rests upon the crural interosseous membrane; in the lower third, upon the front of the tibia and the anterior ligament of the ankle-joint. In the upper third of its course, it lies between the Tibialis anterior and Extensor digitorum longus; in the middle third between the Tibialis anterior and Extensor hallucis longus. At the ankle it is crossed from the lateral to the medial side by the tendon of the Extensor hallucis longus, and lies between it and the first tendon of the Extensor digitorum longus. Its upper two-thirds are covered by the muscles which lie on either side of it, and by the deep fascia; its lower third, by the skin and fascia, and the transverse and cruciate crural ligaments.

A pair of *venæ comitantes* lie one on either side of the artery. The deep peroneal nerve, coursing round the lateral side of the neck of the fibula, comes into relation with the lateral side of the artery shortly after it has reached the front of the leg; about the middle of the leg the nerve is in front of the artery; at the lower part it is generally on the lateral side again.

Peculiarities.—This vessel may be smaller than usual, or may be absent, its place being supplied by perforating branches from the posterior tibial, or by the perforating branch of the peroneal artery. The artery occasionally deviates towards the fibular side of the leg, regaining its usual

position at the front of the ankle. Very occasionally it approaches the surface at the leg, and is covered merely by the skin and fascia below that point.

Applied Anatomy.—The anterior tibial artery is liable to be injured in fractures of the lower third of the tibia, on account of its close proximity to the bone. The application of a ligature to the vessel is rarely required, except in cases of wound or traumatic aneurysm. The operation in the upper half of the leg is difficult on account of the depth of the vessel from the surface. An incision about 10 cm. in length is made 3 cm. lateral to the anterior border of the tibia. The skin and superficial structures having been divided and the deep fascia exposed, the white line separating the Tibialis anterior from the Extensor digitorum longus is sought. When this has been clearly defined, the deep fascia is to be divided in this line, and the Tibialis anterior separated from adjacent muscles until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart the artery will be found lying on the interosseous membrane with the nerve lateral or superficial to it. The nerve should be drawn lateralwards, the venæ comitantes separated from the artery and the needle passed around it.

To tie the vessel in the lower third of the leg, an incision about 7 cm. in length should be made through the skin between the tendons of the Tibialis anterior and Extensor hallucis longus, the deep fascia being divided to the same extent. The tendon on either side should be retracted, when the vessel, accompanied by the venæ comitantes, will be seen lying upon the tibia, with the nerve on the lateral side.

Branches.—The branches of the anterior tibial artery are :

Posterior tibial recurrent.	Anterior medial malleolar.
Anterior tibial recurrent.	Anterior lateral malleolar.
Muscular.	

The **posterior tibial recurrent artery**, an inconstant branch, is given off from the anterior tibial artery before that vessel reaches the front of the leg. It ascends in front of the Popliteus, anastomoses with the inferior genicular branches of the popliteal artery, and gives an offset to the tibiofibular joint.

The **anterior tibial recurrent artery** arises from the anterior tibial artery, as soon as that vessel has reached the front of the limb; it ascends in the Tibialis anterior, ramifies on the front and sides of the knee-joint, and assists in the formation of the patellar network by anastomosing with the genicular branches of the popliteal artery, and with the highest genicular artery.

The **muscular branches** are numerous and are distributed to the muscles which lie on either side of the vessel; some pierce the deep fascia to supply the skin, others pass through the crural interosseous membrane, and anastomose with branches of the posterior tibial and peronæal arteries.

The **anterior medial malleolar artery** (internal malleolar artery) arises about 5 cm. above the ankle-joint, and passes behind the tendons of the Extensor hallucis longus and Tibialis anterior, to the medial side of the ankle, where it anastomoses with branches of the posterior tibial and medial plantar arteries.

The **anterior lateral malleolar artery** (external malleolar artery) passes beneath the tendons of the Extensor digitorum longus and Peronæus tertius; it supplies the lateral side of the ankle and anastomoses with the perforating branch of the peronæal artery and with ascending twigs from the lateral tarsal artery.

The arteries around the ankle-joint anastomose freely with one another and form networks below the corresponding malleoli. The *medial malleolar network* is formed by the anterior medial malleolar branch of the anterior tibial artery, the medial tarsal branches of the dorsalis pedis artery, the posterior medial malleolar and medial calcaneal branches of the posterior tibial artery, and branches from the medial plantar artery. The *lateral malleolar network* is formed by the anterior lateral malleolar branch of the anterior tibial artery, the lateral tarsal branch of the dorsalis pedis artery, the perforating and the lateral calcaneal branches of the peronæal artery, and twigs from the lateral plantar artery.

ARTERIA DORSALIS PEDIS (fig. 659)

The **arteria dorsalis pedis**, the continuation of the anterior tibial artery, passes forwards from the ankle-joint along the tibial side of the dorsum of the foot to the proximal part of the first intermetatarsal space, where it divides into the *first dorsal metatarsal* and the *deep plantar arteries*.

Relations.—The *arteria dorsalis pedis* is accompanied by two veins, and lies successively upon the front of the articular capsule of the ankle-joint, the talus, navicular, and second cuneiform bones, and the ligaments connecting them. It is covered by the skin, fascia, and cruciate crural ligament, and crossed near its termination by the first tendon of the *Extensor digitorum brevis*. On its *tibial side* is the tendon of the *Extensor hallucis longus*; on its *fibular side*, the first tendon of the *Extensor digitorum longus*, and the termination of the deep peroneal nerve.

Peculiarities.—The *arteria dorsalis pedis* may be larger than usual, to compensate for a deficient plantar artery; its branches to the toes may be absent, the toes then being supplied by the medial plantar; or its place may be taken altogether by a large perforating branch of the peroneal artery. It frequently curves lateralwards, lying lateral to the line between the middle of the ankle and the proximal part of the first interosseous space.

Applied Anatomy.—The *arteria dorsalis pedis* may be tied, by making an incision 5 cm. in length, through the skin on the fibular side of the tendon of the *Extensor hallucis longus*, in the interval between it and the medial border of the *Extensor digitorum brevis*. The incision should not extend farther forwards than the proximal part of the first intermetatarsal space, as the artery divides in that situation. When the deep fascia has been divided the artery will be exposed, with the deep peroneal nerve lying lateral to it.

Branches.—The branches of the *arteria dorsalis pedis* are :

Lateral tarsal.
Medial tarsal.

Arcuate.
First dorsal metatarsal.

Deep plantar.

The **lateral tarsal artery** arises from the *arteria dorsalis pedis* as the latter crosses the navicular bone; it passes lateralwards and forms an arch upon the tarsal bones, being covered by the *Extensor digitorum brevis*; it supplies this muscle and the articulations of the tarsus, and anastomoses with branches of the arcuate, anterior lateral malleolar, and lateral plantar arteries, and with the perforating branch of the peroneal artery.

The **medial tarsal arteries** are two or three small branches; they ramify on the medial border of the foot and join the medial malleolar network.

The **arcuate artery** (metatarsal artery) arises a little anterior to the lateral tarsal artery; it passes lateralwards over the bases of the metatarsal bones beneath the tendons of the *Extensor digitorum brevis*, and anastomoses with the lateral tarsal and lateral plantar arteries. It gives off the *second, third, and fourth dorsal metatarsal arteries*, which run forwards upon the corresponding *Interossei dorsales*; in the clefts between the toes each divides into two dorsal digital branches for the adjoining toes. At the proximal parts of the interosseous spaces the dorsal metatarsal arteries receive the posterior perforating branches from the plantar arch, and at the distal parts of the spaces they are joined by the anterior perforating branches from the plantar metatarsal arteries. The fourth dorsal metatarsal artery gives off a branch which supplies the lateral side of the fifth toe.

The **first dorsal metatarsal artery** (*arteria dorsalis hallucis*) runs forward on the first *Interosseus dorsalis*, and at the cleft between the first and second toes divides into two branches, one of which passes beneath the tendon of the *Extensor hallucis longus*, and is distributed to the medial border of the great toe; the other bifurcates to supply the adjoining sides of the great and second toes.

The **deep plantar artery** (communicating artery) descends into the sole of the foot, between the two heads of the first *Interosseus dorsalis*, and completes the plantar arch by uniting with the termination of the lateral plantar artery. At its junction with the lateral plantar artery it gives off the *first plantar metatarsal artery* (p. 669).

POSTERIOR TIBIAL ARTERY (fig. 657)

The **posterior tibial artery** begins at the lower border of the *Popliteus*, opposite the interval between the tibia and fibula, and passes downwards and medialwards on the back of the leg. In the lower part of its course it is situated midway between the medial malleolus and the medial process of the calcaneal tuberosity. It divides beneath the origin of the *Abductor hallucis* into the *medial and lateral plantar arteries*.

Relations.—The posterior tibial artery lies successively upon the Tibialis posterior, the Flexor digitorum longus, the tibia, and the back of the ankle-joint. Its uppermost part is covered by the Gastrocnemius and Soleus and the deep transverse fascia of the leg, its terminal part by the Abductor hallucis. In the lower third of the leg, it is more superficial, and is covered only by the skin and fascia, and runs parallel with the medial border of the tendo calcaneus. It is accompanied by two veins, and by the tibial nerve which lies at first to its medial side, but soon crosses it posteriorly, and is, in the greater part of its course, on its lateral side.

Behind the medial malleolus, the structures which pass under cover of the laciniated ligament are arranged in the following order from the medial to the lateral side; first, the tendons of the Tibialis posterior and Flexor digitorum longus lying in the same groove behind the malleolus, the former being the more medial; then the posterior tibial artery, with a vein on either side of it; lateral to the tibial vessels is the tibial nerve; and about 1.25 cm. nearer the heel is the tendon of the Flexor hallucis longus.

Peculiarities.—The posterior tibial artery may be small or absent, its place being supplied by a large peroneal artery, which either joins the small posterior tibial artery, or continues alone to the sole of the foot.

Applied Anatomy.—Ligature of the posterior tibial artery may be required in cases of wound of the sole of the foot, attended with great hemorrhage; the vessel should then be tied at the ankle. In cases of wound of the posterior tibial, it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurysm from wound of the artery low down, the vessel should be tied in the middle of the leg.

To tie the posterior tibial artery at the ankle, a curved incision, about 6 cm. long, and with its convexity directed backwards, should be made through the skin, midway between the heel and the medial malleolus, or a little nearer the latter. The subcutaneous tissue having been divided, the laciniated (internal annular) ligament is seen. This is divided, and the sheath of the vessels exposed and opened, when the artery is seen with one of the venæ comitantes on either side. The aneurysm needle should be passed round the vessel from the heel towards the ankle, in order to avoid the tibial nerve, care at the same time being taken not to include the venæ comitantes.

The vessel may also be tied in the lower third of the leg by making an incision about 8 cm. long, parallel with the medial border of the tendo calcaneus. The great saphenous vein must be avoided, and the two layers of fascia divided upon a director, when the artery is exposed along the lateral margin of the Flexor digitorum longus, with one of its venæ comitantes on either side, and the nerve lying lateral to it.

Ligature of the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its fibular side, the knee being partially bent, and the foot extended, so as to relax the muscles of the calf. An incision about 10 cm. in length should then be made through the skin, a finger's breadth behind the medial margin of the tibia, care being taken to avoid the great saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and drawn aside, and the tibial attachment of the Soleus divided. The artery may now be felt pulsating beneath the deep transverse fascia, about 2.5 cm. from the margin of the tibia. This fascia having been divided, and the limb placed in such a position as will relax the muscles of the calf as much as possible, the veins should be separated from the artery and the aneurysm needle passed round the vessel from the lateral to the medial side, so as to avoid wounding the tibial nerve.

Branches.—The branches of the posterior tibial artery are:

- | | |
|-------------------|--------------------------------|
| 1. Fibular. | 6. Posterior medial malleolar. |
| 2. Peroneal. | 7. Medial calcaneal. |
| 3. Nutrient. | 8. Medial plantar. |
| 4. Muscular. | 9. Lateral plantar. |
| 5. Communicating. | |

1. The **fibular artery**, sometimes a branch of the anterior tibial artery, passes lateralwards round the neck of the fibula, through the Soleus, and anastomoses with lateral inferior genicular artery.

2. The **peroneal artery** arises from the posterior tibial, about 2.5 cm. below the lower border of the Popliteus. It passes obliquely towards the fibula, and descends along the medial side of that bone, contained in a fibrous canal between the Tibialis posterior and the Flexor hallucis longus, or in the substance of the

latter muscle. It then runs behind the inferior tibiofibular joint, and divides into lateral calcaneal branches which ramify on the lateral and posterior surfaces of the calcaneus.

It is covered, in the *upper* part of its course, by the Soleus and deep transverse fascia of the leg; in the *lower* part, by the Flexor hallucis longus.

Peculiarities.—The peronæal artery may arise 7 or 8 cm. below the Popliteus, or from the posterior tibial high up, or even from the popliteal. It is more frequently increased than diminished in size; and then it either joins and reinforces the posterior tibial artery, or takes the place of that artery in the lower part of the leg and foot. When the peronæal artery is smaller than usual, a branch from the posterior tibial artery supplies its place; and a branch from the anterior tibial artery compensates for the diminished perforating artery.

The peronæal artery gives off the following branches:

Muscular branches are supplied to the Soleus, Tibialis posterior, Flexor hallucis longus, and Peronæi.

A *nutrient artery* supplies the fibula, and is directed downwards.

A *perforating branch* pierces the crural interosseous membrane, about 5 cm. above the lateral malleolus, and reaches the front of the leg, where it anastomoses with the anterior lateral malleolar; it then passes down in front of the inferior tibiofibular joint, gives branches to the tarsus, and anastomoses with the lateral tarsal artery. The perforating branch is sometimes enlarged, and may take the place of the dorsalis pedis artery.

A *communicating branch* arises from the peronæal artery about 5 cm. above the lower end of the tibia, and joins the communicating branch of the posterior tibial artery.

Lateral calcaneal or terminal branches of the peronæal artery pass to the lateral side of the heel, and communicate with the anterior lateral malleolar artery and, on the back of the heel, with the medial calcaneal arteries.

3. The **nutrient artery** of the tibia arises from the posterior tibial artery near its origin, and, after supplying a few minute muscular branches, enters the nutrient canal in the bone; this canal is situated immediately below the popliteal line and is directed downwards.

4. **Muscular branches** are distributed to the Soleus and to the deep muscles on the back of the leg.

5. The **communicating branch** runs transversely across the back of the tibia about 5 cm. above its lower end, beneath the Flexor hallucis longus, and joins the communicating branch of the peronæal artery.

6. The **posterior medial malleolar artery** is a small branch which winds round the tibial malleolus and ends in the media' malleolar network.

7. The **medial calcaneal branches** are several large arteries which arise from the posterior tibial just before its division; they pierce the lacinate ligament and are distributed to the fat and skin behind the tendo calcaneus and about the heel, and to the muscles on the tibial side of the sole, anastomosing with the peronæal and medial malleolar arteries, and, on the back of the heel, with the lateral calcaneal arteries.

8. The **medial plantar artery** (internal plantar artery) (figs. 660, 661), the smaller of the terminal branches of the posterior tibial artery, passes forwards along the medial side of the foot. It is at first situated above the Abductor hallucis, and then between it and the Flexor digitorum brevis, both of which it supplies. At the base of the first metatarsal bone, where it is much diminished in size, it passes along the medial border of the first toe and anastomoses with the first dorsal metatarsal artery. Three small superficial digital branches accompany the digital branches of the medial plantar nerve and join the first, second and third plantar metatarsal arteries.

9. The **lateral plantar artery** (external plantar artery) (fig. 661), the larger of the terminal branches of the posterior tibial artery, passes at first obliquely lateralwards and forwards to the base of the fifth metatarsal bone in company with the lateral plantar nerve. It then turns medialwards with the deep branch of the nerve, to the interval between the bases of the first and second metatarsal bones, where it unites with the deep plantar branch of the dorsalis pedis artery, thus completing the *plantar arch*. As this artery passes lateralwards, it is first placed between the calcaneus and Abductor hallucis, and then between the Flexor digitorum brevis and Quadratus plantæ; as it runs forwards to the base of the fifth metatarsal bone it lies between the Flexor digitorum brevis and Abductor digiti quinti, and is covered by the plantar aponeurosis superficial fascia and skin. The remainder of the vessel is deeply situated; it extends from the base of the fifth metatarsal bone to

the proximal part of the first interosseous space, and forms the plantar arch ; it is convex forwards, lies below the bases of the second, third, and fourth metatarsal bones and the corresponding Interossei and upon the oblique part of the Adductor hallucis.

Branches.—The plantar arch distributes numerous twigs to the skin, fasciæ and muscles in the sole, and gives off the following branches :

(a) **Perforating branches**, three in number, ascend through the proximal part of the second, third, and fourth interosseous spaces, between the heads of the Interossei dorsales, and anastomose with the dorsal metatarsal arteries.

FIG. 660.—The plantar arteries.
Superficial view.

FIG. 661.—The plantar arteries.
Deep view.

(b) **Plantar metatarsal arteries** (fig. 661), four in number, run forwards between the metatarsal bones and in contact with the Interossei. Each divides into a pair of plantar digital arteries which supply the adjacent sides of the toes. Near their points of division each sends upwards an *anterior perforating branch* to join the corresponding dorsal metatarsal artery. The first plantar metatarsal artery (*arteria magna hallucis*) springs from the junction between the lateral and deep plantar arteries (p. 666), and sends a digital branch to the medial side of the first toe. The digital branch for the lateral side of the fifth toe arises from the lateral plantar artery near the base of the fifth metatarsal bone.

Applied Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. They must be treated on similar lines to those of wounds of the volar arches (p. 627). Pressure locally, combined with elevation of the limb, may in some cases be sufficient to arrest the bleeding, but if this fails, an attempt should be made to find the bleeding point and ligature it. Should this prove unsuccessful, it may be necessary to ligature the femoral artery below the origin of the *arteria profunda femoris*, as ligature of the anterior and posterior tibial arteries may not be sufficient to control the hæmorrhage, and it is safer and quicker to tie the femoral under the circumstances.

THE VEINS

The veins convey the blood from the capillaries of the different parts of the body to the heart. They consist of two sets, *pulmonary* and *systemic*.

The **pulmonary veins**, unlike other veins, contain arterial blood, which they return from the lungs to the left atrium of the heart.

The **systemic veins** return the venous blood from the body generally, to the right atrium of the heart.

The **portal vein**, an appendage to the systemic venous system, is confined to the abdominal cavity, and conveys the venous blood from the spleen and the viscera of digestion to the liver, where it breaks up into a network of capillary-like vessels, from which the blood is drained by the hepatic veins to the inferior vena cava.

The veins receive the blood from the capillaries, and unite with one another to form larger vessels which, in their passage towards the heart, increase in size as they receive tributaries, or join other veins. The veins are larger and more numerous than the arteries; hence, the capacity of the veins is greater than that of the arteries; the capacity of the pulmonary veins, however, only slightly exceeds that of the pulmonary arteries. The veins are cylindrical like the arteries; their walls, however, are thin and they collapse when the vessels are empty, and the uniformity of their surfaces is interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior (p. 550). They communicate very freely with one another, especially in certain regions of the body. Thus, between the venous sinuses of the cranium, and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral circulation, large and frequent anastomoses are found. Free communications also exist between the veins of the vertebral canal, and between the veins composing the various venous plexuses in the abdomen and pelvis.

The systemic venous channels are subdivided into three sets, viz. superficial and deep veins, and venous sinuses.

The **superficial veins** lie in the superficial fascia, beneath the skin; they return the blood from these structures, and communicate with the deep veins.

The **deep veins** accompany the arteries, and are usually enclosed in the same sheaths with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on either side of the artery, and are called *venæ comitantes*. The larger arteries—such as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain regions, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and vertebral canal, the hepatic veins in the liver, and the larger veins returning blood from the bones.

Venous sinuses are found only in the interior of the skull, and are canals between the two layers of the dura mater.

PULMONARY VEINS

The **pulmonary veins** return the arterialised blood from the lungs to the left atrium of the heart. They are four in number, two from each lung, and are destitute of valves. They commence in a capillary network upon the walls of the alveoli of the lungs, where they are continuous with the capillary ramifications of the pulmonary arteries, and, joining together, form one vessel from each lobule of the lung. These vessels, uniting successively, form a single trunk from each lobe, three from the right lung and two from the left. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, so that ultimately two trunks from each lung are formed; they perforate the fibrous layer of the pericardium and open separately into the upper and posterior part of the left atrium. Occasionally the three veins on the right side remain separate. Sometimes the two left pulmonary veins end by a common opening.

At the root of the lung, the superior pulmonary vein lies in front of and a little below the pulmonary artery; the inferior is situated at the lowest part of the hilum of the lung and on a plane posterior to the upper vein. Behind the pulmonary artery is the bronchus.

The right pulmonary veins pass behind the right atrium and superior vena cava; the left in front of the descending thoracic aorta.

Within the pericardium, their anterior surfaces are invested by the serous layer of this membrane.

THE SYSTEMIC VEINS

The **systemic veins** may be arranged into three groups: 1. The veins of the heart. 2. The veins of the upper extremities, head, neck, and thorax, which end in the superior vena cava. 3. The veins of the lower extremities, abdomen, and pelvis, which end in the inferior vena cava.

VEINS OF THE HEART (fig. 662)

Coronary sinus.—Most of the veins of the heart open into the coronary sinus. This is a wide venous channel about 2.25 cm. long, situated in the

FIG. 662.—Base and diaphragmatic surface of heart.

posterior part of the coronary sulcus of the heart, between the left atrium and left ventricle, and covered by muscular fibres from the left atrium. It ends in the right atrium between the opening of the inferior vena cava and the atrio-ventricular orifice, its aperture being guarded by a semilunar valve, the *valve of the coronary sinus* (valve of Thebesius).

Its tributaries are the great, small, and middle cardiac veins, the posterior vein of the left ventricle, and the oblique vein of the left atrium, all of which, except the last, are provided with valves at their orifices.

1. The **great cardiac vein** begins at the apex of the heart and ascends in the anterior longitudinal sulcus to the bases of the ventricles. It then curves to the left in the coronary sulcus, and, reaching the back of the heart, opens into the left extremity of the coronary sinus. It receives tributaries from the left atrium and from both ventricles: one, the *left marginal vein*, is of considerable size, and ascends along the left margin of the heart.

2. The **small cardiac vein** runs in the coronary sulcus between the right atrium and ventricle, and opens into the right extremity of the coronary sinus. It receives blood from the back of the right atrium and ventricle; the *right marginal vein* ascends along the right margin of the heart and joins the small cardiac vein in the coronary sulcus, or opens directly into the right atrium.

3. The **middle cardiac vein** begins at the apex of the heart, ascends in the posterior longitudinal sulcus, and ends in the coronary sinus near its right extremity.

4. The **posterior vein of the left ventricle** runs on the diaphragmatic surface of the left ventricle to the coronary sinus, but may end in the great cardiac vein.

5. The **oblique vein of the left atrium** (oblique vein of Marshall) is a small vessel which descends obliquely on the back of the left atrium and ends in the coronary sinus near its left extremity; it is continuous above with the *ligament of the left vena cava* (vestigial fold of Marshall), and the two structures are remnants of the left duct of Cuvier.

The following cardiac veins do not end in the coronary sinus: (1) the **anterior cardiac veins**, comprising three or four small vessels which collect blood from the front of the right ventricle and open into the right atrium; the right marginal vein frequently opens into the right atrium, and is therefore sometimes regarded as belonging to this group; (2) the **smallest cardiac veins** (vv. cordis minimæ), consisting of a number of minute veins which arise in the muscular wall of the heart; most of them open into the atria, but a few end in the ventricles.

VEINS OF THE HEAD AND NECK

The veins of the head and neck may be subdivided into three groups:

1. The veins of the exterior of the head and face.
2. The veins of the neck.
3. The diploic veins, the veins of the brain, and the venous sinuses of the dura mater.

VEINS OF THE EXTERIOR OF THE HEAD AND FACE (fig. 663)

Frontal.	Superficial temporal.
Supraorbital.	Internal maxillary.
Angular.	Posterior facial.
Anterior facial.	Posterior auricular.
	Occipital.

The **frontal vein** begins on the forehead in a venous network which communicates with the frontal tributaries of the superficial temporal vein. Veins converge from the network to form a single trunk, which descends near the middle line of the forehead parallel with the vein of the opposite side. At the root of the nose the two veins are joined by a transverse branch which is called the *nasal arch* and receives some small veins from the dorsum of the nose. The frontal veins then diverge, and at the medial angle of the orbit, each joins with the *supraorbital vein* to form the *angular vein*. Occasionally the frontal veins unite in a single trunk, which bifurcates at the root of the nose into two angular veins.

The **supraorbital vein** begins on the forehead, where it communicates with the frontal tributary of the superficial temporal vein. It descends superficially to the Frontalis muscle, and at the medial angle of the orbit joins the frontal vein to form the *angular vein*; it receives the frontal diploic vein, and communicates with the superior ophthalmic vein.

The **angular vein**, formed by the junction of the frontal and supraorbital veins, runs obliquely downwards on the side of the root of the nose, to the level of the lower margin of the orbit, where it becomes the anterior facial vein. It receives the veins of the ala nasi, and communicates with the superior ophthalmic vein through the nasofrontal vein, thus establishing an anastomosis between the anterior facial vein and the cavernous sinus.

FIG. 663.—Veins of the head and neck.

The **anterior facial vein** (facial vein) begins at the side of the nose as a direct continuation of the angular vein. It lies behind the external maxillary (facial) artery and follows a less tortuous course. It runs obliquely downwards and backwards, beneath the *Zygomaticus* and zygoma, head of the *Quadratus labii superioris*, descends along the anterior border and then on the superficial surface of the *Masseter*, crosses over the body of the mandible, and passes obliquely backwards, beneath the *Platysma* and cervical fascia, superficial to the submaxillary gland, *Digastricus*, and *Stylohyoideus*. It unites with the anterior branch of the posterior facial vein to form the **common facial vein**, which crosses the external carotid artery and enters the internal jugular vein at a variable point below the hyoid bone. From near its termination a branch, often runs down the anterior border of the *Sternocleidomastoideus* to join the lower part of the anterior jugular vein.

ANGIOLOGY

Tributaries.—The anterior facial vein receives a branch of considerable size, the *deep facial vein*, from the pterygoid venous plexus. It is also joined by the superior and inferior palpebral, the superior and inferior labial, the buccinator and the masseteric veins. Below the mandible it receives the submental, palatine, and submaxillary veins, and, generally also, the vena comitans of the hypoglossal nerve.

Applied Anatomy.—There are some points about the anterior facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by the angular and supraorbital veins which are connected with the ophthalmic vein, a tributary of the cavernous sinus, but also by the deep facial vein, which communicates through the pterygoid plexus with the cavernous sinus by branches passing through the foramen ovale and foramen lacerum (p. 687). These facts have an important bearing upon the surgery of some diseases; any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the anterior facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. These thrombi may extend upwards into the cranial sinuses, and so induce a fatal issue; this has been known to follow in cases of ordinary carbuncle of the face. The position of the vein must be borne in mind when incisions are made for the relief of suppuration about the mandible.

The **superficial temporal vein** begins on the side and vertex of the skull in a network which joins with the corresponding vein of the opposite side, and with the frontal, supraorbital, posterior auricular and occipital veins. From this network, frontal and parietal branches arise, and unite above the zygomatic arch to form the superficial temporal vein, which is joined in this situation by the *middle temporal vein*, from the substance of the Temporalis muscle. It then crosses the posterior root of the zygomatic arch, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the posterior facial vein.

Tributaries.—The superficial temporal vein receives some veins from the parotid gland, articular veins from the temporomandibular joint, anterior auricular veins from the auricula, and the *transverse facial* from the side of the face. The middle temporal vein receives the *orbital vein*, which is formed by some lateral palpebral branches, and passes backwards between the layers of the temporal fascia to join the superficial temporal vein.

The **pterygoid plexus** is of considerable size, and is situated partly between the Temporalis and Pterygoideus externus, and partly between the two Pterygoidei. Its tributaries correspond with the branches of the internal maxillary artery; thus, it receives the sphenopalatine, middle meningeal, deep temporal, pterygoid, masseteric, buccinator, alveolar, and some palatine veins, and a branch which communicates with the inferior ophthalmic vein through the inferior orbital fissure. The pterygoid plexus anastomoses with the anterior facial vein, through the deep facial vein; it is also connected with the cavernous sinus by veins which pass through the foramen Vesalii, foramen ovale, and foramen lacerum.

The **internal maxillary vein** is a short trunk which accompanies the first part of the internal maxillary artery and is formed by a confluence of the veins of the pterygoid plexus. It passes backwards between the sphenomandibular ligament and the neck of the mandible, and unites with the temporal vein to form the posterior facial vein.

The **posterior facial vein** (temporomaxillary vein), formed by the union of the superficial temporal and internal maxillary veins, descends in the substance of the parotid gland, superficial to the external carotid artery but deep to the facial nerve, between the ramus of the mandible and the Sternocleidomastoideus muscle. It divides into two branches, an anterior, which passes forwards and unites with the anterior facial vein to form the common facial vein, and a posterior, which is joined by the posterior auricular vein and becomes the external jugular vein.

The **posterior auricular vein** begins upon the side of the head, in a network which communicates with the tributaries of the occipital and superficial temporal veins. It descends behind the auricula, and joins the posterior division of the posterior facial vein to form the external jugular vein. It receives the stylomastoid vein and some tributaries from the cranial surface of the auricula.

The **occipital vein** begins in a venous network at the posterior part of the skull. It pierces the cranial attachment of the Trapezius, dips into the suboccipital triangle

and joins the deep cervical and vertebral veins. Occasionally it follows the course of the occipital artery and ends in the internal jugular vein; sometimes it joins the posterior auricular vein and through it opens into the external jugular vein. The parietal emissary vein connects it with the superior sagittal sinus, and the mastoid emissary vein with the transverse sinus. The occipital diploic vein sometimes joins it.

VEINS OF THE NECK (fig. 663)

External jugular. Anterior jugular.
Posterior external jugular. Internal jugular.
Vertebral.

The **external jugular vein** receives the greater part of the blood from the exterior of the cranium and from the deep parts of the face, and is formed by the union of the posterior division of the posterior facial vein with the posterior auricular vein. It begins in the substance of the parotid gland, on a level with the angle of the mandible, and runs down the neck, where its course is represented by a line drawn from the angle of the mandible to the middle of the clavicle at the posterior border of the *Sternocleidomastoideus*. It crosses the *Sternocleidomastoideus* obliquely, and in the subclavian triangle perforates the deep fascia, and ends in the subclavian vein, lateral to or in front of the *Scalenus anterior*. It is separated from the *Sternocleidomastoideus* by the investing layer of the deep cervical fascia, and is covered by the *Platysma*, superficial fascia, and skin; it crosses the cutaneous cervical nerve, and its upper half runs parallel with the great auricular nerve. The external jugular vein varies in size, bearing an inverse proportion to the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, a lower pair at its entrance into the subclavian vein, an upper about 4 cm. above the clavicle. The portion of the vein between the two sets of valves is often dilated, and is termed the *sinus*. These valves do not prevent regurgitation of the blood, or the passage of injection from below upwards.

Tributaries.—This vein receives the posterior external jugular, and, near its termination, the transverse cervical, transverse scapular, and anterior jugular veins; in the substance of the parotid gland, a large branch from the internal jugular joins it. The occipital vein occasionally opens into it.

The **posterior external jugular vein** begins in the occipital region and returns the blood from the skin and superficial muscles in the upper and posterior part of the neck. It opens into the middle part of the external jugular vein.

The **anterior jugular vein** is devoid of valves and begins near the hyoid bone by the confluence of several superficial veins from the submaxillary region. It descends between the median line and the anterior border of the *Sternocleidomastoideus*, and, at the lower part of the neck, turns lateralwards beneath that muscle to open into the termination of the external jugular vein, or into the subclavian vein (figs. 663, 664). It varies considerably in size, bearing usually an inverse proportion to the external jugular; most frequently there are two anterior jugulars, a right and left; but sometimes only one. It communicates with the internal jugular vein and receives as tributaries some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum, the two anterior jugular veins are united to one another by a transverse trunk, the *venous jugular arch*, which receives tributaries from the inferior thyroid veins.

Applied Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. The point to be remembered in performing this operation is to cut across the fibres of the *Platysma* in opening the vein, so that by their contraction they will expose the orifice in the vein and so allow the flow of blood.

The **internal jugular vein** collects the blood from the brain, from the superficial parts of the face, and from the neck. It is directly continuous with the transverse sinus of the cranium, and begins at the base of the skull in the posterior compartment of the jugular foramen. At its origin it is somewhat dilated, and this dilatation is called the *superior bulb*. It runs down the side of the neck, lying at first laterally to the internal carotid artery, and then laterally

to the common carotid artery. At the root of the neck it unites with the subclavian vein to form the innominate vein; a little above its termination is a second dilatation, the *inferior bulb*. In the upper part of its course, it lies upon the Rectus capitis lateralis, behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glossopharyngeal and hypoglossal nerves passing forwards between them; the vagus nerve descends in the same sheath as the vein and artery, but lies between and on a plane posterior to them; the accessory nerve runs obliquely backwards, superficial or deep to the vein. At the root

FIG. 664.—The veins of the neck, viewed from in front. (After Spalteholz.)

of the neck the right internal jugular vein is placed at a little distance from the common carotid artery, and crosses the first part of the subclavian artery, while the left internal jugular vein usually overlaps the common carotid artery. The left vein is generally smaller than the right, and each contains a pair of valves, which are placed about 2.5 cm. above the termination of the vessel.

Tributaries.—The internal jugular vein receives the inferior petrosal sinus, the common facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital vein. The thoracic duct opens into the angle of union of the left subclavian and internal jugular veins, and the right lymphatic duct into the angle of union of the right subclavian and internal jugular veins.

The **inferior petrosal sinus** leaves the skull through the anterior part of the jugular foramen, and joins the superior bulb of the internal jugular vein.

The **lingual veins** begin on the dorsum, sides, and under surface of the tongue, and, passing backwards along the course of the lingual artery, end in the internal jugular vein. The **vena comitans hypoglossi** (ranine vein), a branch of considerable size, begins below the tip of the tongue, and may join the lingual veins; generally, however, it passes backwards superficially to the Hyoglossus, and opens into the common facial vein.

The **pharyngeal veins** begin in the *pharyngeal plexus* on the outer surface of the pharynx, and, after receiving some posterior meningeal veins and the vein of the pterygoid canal, end in the internal jugular vein. They occasionally open into the facial, the lingual, or the superior thyroid vein.

The **superior thyroid vein** (fig. 665) begins in the substance and on the surface of the thyroid gland, by tributaries corresponding with the branches of the superior thyroid artery, and ends in the upper part of the internal jugular vein. It receives the superior laryngeal and cricothyroid veins.

FIG. 665.—The veins of the thyroid gland.

The **middle thyroid vein** (fig. 665) collects the blood from the lower part of the thyroid gland, receives some veins from the larynx and trachea, and ends in the lower part of the internal jugular vein.

The **common facial and occipital veins** have been described.

Applied Anatomy.—The internal jugular vein requires ligature in cases of septic thrombosis of the transverse sinus, in order to prevent septic emboli being carried into the general circulation. This operation has been performed in many cases, with the most satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and setting up septic thrombosis of the transverse sinus and extending downwards into the internal jugular vein. Such cases are always extremely grave, for there is a danger of porticus of the thrombus or clot being detached and causing septic embolism in the lungs. If the condition be suspected, the diseased bone should be removed at once from the mastoid process. The sinus is then investigated, and if it be found thrombosed, the surgeon should proceed to ligature the internal jugular vein, through an incision along the anterior

border of the Sternocleidomastoideus, the centre of the incision being on a level with the greater cornu of the hyoid bone. The vein should be ligatured in two places and divided between. After the vessel has been secured and divided, the transverse sinus is to be thoroughly cleared out, and, by removing the ligature from the upper end of the divided vein, all septic clots removed by syringing from the sinus through the vein. If hæmorrhage occur from the distal end of the sinus, it can be arrested by careful plugging with antiseptic gauze.

The internal jugular vein is also surgically important, because it is surrounded by a number of deep cervical lymph-glands; and when these are enlarged in tuberculous or malignant disease, they are apt to adhere to the vessel, rendering their removal difficult and often dangerous. The proper course to pursue in these cases is to ligature the vessel above and below the glandular mass, and remove the included portion with the glands.

Cardiac pulsation is often demonstrable in the internal jugular vein at the root of the neck. There are no valves in the innominate veins or superior vena cava; in consequence, the systole of the right atrium causes a wave to pass up these vessels, and when the conditions are favourable this wave appears as a somewhat feeble flicker over the internal jugular vein at the root of the neck, quite distinct from, and just preceding, the more forcible impulse transmitted from the underlying common carotid artery and due to the ventricular systole. This atrial systolic venous impulse is much increased in conditions in which the right atrium is abnormally distended with blood or is hypertrophied, as is often the case in disease of the bicuspid valve. In the Adam-Stokes' syndrome (p. 565) it is this pulsation which gives evidence of the fact that the atria are beating faster—often two or three times faster—than the ventricles.

The **vertebral vein** is formed in the suboccipital triangle, from numerous small tributaries which spring from the internal vertebral venous plexuses and issue from the vertebral canal above the posterior arch of the atlas. They unite with small veins from the deep muscles at the upper part of the back of the neck, and form a vessel which enters the foramen in the transverse process of the atlas, and descends, forming a dense plexus around the vertebral artery, in the canal formed by the foramina transversaria of the cervical vertebræ. This plexus ends in the vertebral vein, which emerges from the foramen transversarium of the sixth cervical vertebra, and opens into the upper and posterior part of the innominate vein, the opening being guarded by a pair of valves. On the right side, it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein communicates with the transverse sinus of the skull by a vein which passes through the condyloid canal, when that canal exists. It receives branches from the occipital vein, from the prevertebral muscles, and from the internal and external vertebral venous plexuses. It is joined by the anterior vertebral and the deep cervical veins; close to its termination it sometimes receives the first intercostal vein.

The **anterior vertebral vein** commences in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending cervical artery between the Scalenus anterior and Longus capitis muscles, and opens into the terminal part of the vertebral vein.

The **deep cervical vein** accompanies its artery between the Semispinales capitis and colli. It begins in the suboccipital region by communicating branches from the occipital vein and by small veins from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebræ, and passes forwards between the transverse process of the seventh cervical vertebra and the neck of the first rib to end in the lower part of the vertebral vein.

DIPLOIC VEINS (fig. 666)

The diploic veins occupy channels in the diploë of the cranial bones.

They are large, and exhibit at irregular intervals pouch-like dilatations; their walls are thin, and formed of endothelium supported by a layer of elastic tissue.

They communicate with the meningeal veins, the sinuses of the dura mater, and the veins of the pericranium. They consist of (1) the *frontal diploic vein*, which opens into the supraorbital vein and the superior sagittal sinus; (2) the *anterior temporal diploic vein*, which is confined chiefly to the frontal bone, and pierces the great wing of the sphenoidal bone to end in the sphenoparietal sinus or in the anterior deep temporal vein; (3) the *posterior temporal diploic vein*, which is situated in the parietal bone; it descends to the mastoid angle

of the parietal bone, and joins the transverse sinus through an aperture at the mastoid angle of the parietal bone or through the mastoid foramen; and

FIG. 666.—Veins of the diploë as displayed by the removal of the outer table of the skull.

(4) the *occipital diploic vein*, the largest of the four, which is confined to the occipital bone, and opens into the occipital vein or into the transverse sinus.

VEINS OF THE BRAIN

The veins of the brain possess no valves, and their walls, owing to the absence of muscular tissue, are extremely thin. They pierce the arachnoid membrane and the inner or meningeal layer of the dura mater, and open into the cranial venous sinuses. They consist of two sets, cerebral and cerebellar.

The **cerebral veins** are divisible into external and internal groups according as they drain the outer surfaces or the inner parts of the hemispheres.

The **external cerebral veins** are the superior, middle, and inferior.

The *superior cerebral veins*, eight to twelve in number, drain the superior, lateral, and medial surfaces of the hemispheres, and are mainly lodged in the sulci between the gyri, but some run across the gyri. They open into the superior sagittal sinus; the anterior veins run nearly at right angles to the sinus; the posterior and larger veins are directed obliquely forwards, and thus open into the sinus in a direction more or less opposed to the current of the blood contained within it.

The *middle cerebral vein* (superficial Sylvian vein) begins on the lateral surface of the hemisphere, and, running along the lateral cerebral fissure, ends in the cavernous sinus or the sphenoparietal sinus. It is connected (a) with the superior sagittal sinus by the *great anastomotic vein of Trolard*, which opens into one of the superior cerebral veins; (b) with the transverse sinus by the *posterior anastomotic vein of Labbé*, which courses over the temporal lobe.

The *inferior cerebral veins*, of small size, drain the under surfaces of the hemispheres. Those on the orbital surface of the frontal lobe join the superior cerebral veins, and through these open into the superior sagittal sinus; those of the temporal lobe anastomose with the basal and middle cerebral veins, and join the cavernous sphenoparietal, and superior petrosal sinuses.

The **basal vein** is formed at the anterior perforated substance by the union of (a) a small *anterior cerebral vein* which accompanies the anterior cerebral artery, (b) the *deep middle cerebral vein* (deep Sylvian vein), which receives tributaries

from the insula and neighbouring gyri, and runs in the lower part of the lateral cerebral fissure, and (c) the *inferior striate veins* which leave the corpus striatum through the anterior perforated substance. The basal vein passes backwards round the cerebral peduncle, and ends in the internal cerebral vein (vein of Galen); it receives tributaries from the interpeduncular fossa, the inferior horn of the lateral ventricle, the hippocampal gyrus, and the mid-brain.

The *internal cerebral veins* (veins of Galen), two in number, drain the deep parts of the hemisphere; each is formed near the interventricular foramen by the union of the *terminal* and *chorioid veins*. They run backwards parallel with one another, between the layers of the tela chorioidea of the third ventricle, and beneath the splenium of the corpus callosum, where they unite to form a short trunk, the *great cerebral vein*; just before their union each receives the corresponding basal vein.

The *terminal vein* (*vena corporis striati*) runs in the groove between the corpus striatum and thalamus, receives numerous veins from both of these structures, and unites behind the crus fornicis with the chorioid vein, to form one of the internal cerebral veins. The *chorioid vein* runs along the whole length of the chorioid plexus, and receives veins from the hippocampus, the fornix, and the corpus callosum.

The *great cerebral vein* (*vena magna Galeni*), formed by the union of the two internal cerebral veins, is a short median trunk which curves backwards and upwards around the splenium of the corpus callosum and ends in the anterior extremity of the straight sinus.

The *cerebellar veins* are placed on the surface of the cerebellum, and consist of two sets, superior and inferior. The *superior cerebellar veins* pass partly forwards and medialwards, across the superior vermis, to end in the straight sinus and the internal cerebral veins, partly lateralwards to the transverse and superior petrosal sinuses. The *inferior cerebellar veins*, of large size, end in the transverse, superior petrosal, and occipital sinuses.

VENOUS SINUSES OF THE DURA MATER

The sinuses of the dura mater are venous channels which drain the blood from the brain; they are situated between the two layers of the dura mater and are lined by endothelium continuous with that which lines the veins; they contain no valves and their walls are devoid of muscular tissue. They may be divided into two groups: (1) a posterosuperior, at the upper and posterior part of the skull, and (2) an antero-inferior, at the base of the skull.

Posterosuperior group:

Superior sagittal.

Inferior sagittal.

Straight.

Two transverse.

Occipital.

The *superior sagittal sinus* (superior longitudinal sinus) (figs. 667, 668) occupies the attached or convex margin of the falx cerebri. (Commencing at the foramen cæcum, through which it receives a vein from the nasal cavity, it runs backwards, grooving the inner surface of the frontal bone, the adjacent margins of the two parietal bones, and the superior division of the cruciate eminence of the occipital bone; near the internal occipital protuberance it deviates to one or other side (usually the right), and is continued as the corresponding transverse sinus.) It is triangular in section, and gradually increases in size as it passes backwards. On its inner surface are the openings of the superior cerebral veins, and numerous fibrous bands (*chordæ Willisii*) which cross the inferior angle of the sinus; the sinus also communicates through small openings with irregularly-shaped *venous lacunæ* in the dura mater near the sinus. There are usually three venous lacunæ on either side of the sinus: a small frontal, a large parietal, and an occipital which is intermediate in size between the other two (Sargent *). Many of the cerebral veins from the lateral surface of the hemisphere open into these lacunæ, and numerous arachnoidal granulations (Pacchionian bodies) project into them from below. (The superior

* *Journal of Anatomy and Physiology*, vol. xlv.

sagittal sinus receives the superior cerebral veins, veins from the diploë and dura mater, and, near the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina.)

Applied Anatomy.—The numerous communications which take place between this sinus and the veins of the nose, scalp, and diploë, cause it to be at times the seat of infective thrombosis from suppurative processes in these parts.

The inferior sagittal sinus (inferior longitudinal sinus) (fig. 668) is contained in the posterior half or two-thirds of the free margin of the falx cerebri. It increases in size as it passes backwards, and ends in the straight sinus. It

FIG. 667.—Superior sagittal sinus laid open after removal of the skull-cap. The chordæ Willisii and venous lacunæ are clearly seen; from two of the lacunæ probes are passed into the sinus. (Poirier and Charpy.)

receives several veins from the falx cerebri, and occasionally a few from the medial surfaces of the hemispheres.

The straight sinus (figs. 668, 669) is situated at the line of junction of the falx cerebri with the tentorium cerebelli. It is triangular in section, and runs backwards and downwards from the end of the inferior sagittal sinus to the transverse sinus of the side opposite to that into which the superior sagittal sinus is prolonged. Its terminal part communicates by a cross branch with the confluence of the sinuses. Besides the inferior sagittal sinus, it receives the great cerebral vein (vena magna Galeni) and some of the superior cerebellar veins. A few transverse bands cross its interior.

The transverse sinuses (lateral sinuses) (figs. 669, 670) are of large size, and begin at the internal occipital protuberance; one, generally the right, being the direct continuation of the superior sagittal sinus, the other of the straight sinus. Each transverse sinus passes lateralwards and forwards, describing a slight curve with its convexity upwards, to the base of the petrous portion of the temporal bone and lies, in this part of its course, in the attached

margin of the tentorium cerebelli; it then leaves the tentorium and curves downwards and medialwards to reach the posterior part of the jugular foramen, through which it passes, and ends in the internal jugular vein. It rests successively upon the squama of the occipital bone, the mastoid angle of the parietal bone, the mastoid part of the temporal bone, and the jugular process of the occipital bone; the portion which occupies the groove on the mastoid part of the temporal bone is sometimes termed the *sigmoid sinus*. The transverse sinuses are frequently of unequal size, that formed by the superior sagittal

FIG. 668.—Dura mater and its processes, exposed by removing part of the right half of the skull, and the brain.

sinus being the larger; they increase in size as they proceed from behind forwards. On transverse section the horizontal portion of the sinus exhibits a prismatic, the curved portion a semicylindrical, form. They communicate with the veins of the pericranium by means of the mastoid and condyloid emissary veins, and receive the superior petrosal sinuses, some inferior cerebral, inferior cerebellar and diploic veins. The *petrosquamous sinus*, when present, runs backwards along the junction of the squama and petrous portion of the temporal bone, and opens into the transverse sinus.

The *occipital sinus* (fig. 670), the smallest of the cranial sinuses, is situated in the attached margin of the falx cerebelli, and is generally single, but occasionally there are two. It commences around the margin of the foramen magnum by several small venous channels, one of which joins the terminal part of the transverse sinus; it communicates with the posterior internal vertebral venous plexuses, and ends in the confluence of the sinuses.

The *confluence of the sinuses*, or *torcular Herophili*, is the term applied to the dilated extremity of the superior sagittal sinus. It is lodged on one side (generally the right) of the internal occipital protuberance, and from it the transverse sinus of the same side is derived. It receives also the blood from the occipital sinus, and is connected by a channel with the commencement of the opposite transverse sinus.

FIG. 669.—Tentorium cerebelli from above.

2. Antero-inferior group:

Two cavernous.

Two intercavernous.

Two superior petrosal.

Two inferior petrosal.

Basilar plexus.

The **cavernous sinuses** (figs. 670, 671) are so named because they present a **reticulated structure**, due to their being traversed by numerous interlacing **filaments**. They are of irregular form, larger behind than in front, and are placed one on either side of the body of the sphenoidal bone, extending from the superior orbital fissure to the apex of the petrous portion of the temporal bone; they open behind into the petrosal sinuses. On the medial wall of each sinus is the internal carotid artery, accompanied by filaments of the carotid plexus; near the artery is the abducent nerve; on the lateral wall are the oculomotor and trochlear nerves, and the ophthalmic and maxillary divisions of the trigeminal nerve (fig. 671). These structures are separated from the blood in the sinus by the lining membrane of the sinus.

The cavernous sinus receives the superior ophthalmic vein, and a branch from the inferior ophthalmic vein, through the superior orbital fissure, some of the inferior cerebral veins, and also the *sphenoparietal sinus* which courses along the under surface of the small wing of the sphenoid. It communicates with the transverse sinus by means of the superior petrosal sinus; with the

internal jugular vein through the inferior petrosal sinus and a plexus of veins on the internal carotid artery; with the pterygoid venous plexus by veins which pass through the foramen Vesalii, foramen ovale, and foramen lacerum, and with the angular vein through the superior ophthalmic vein. The two sinuses also communicate with each other by means of the anterior and posterior intercavernous sinuses and the basilar plexus.)

Applied Anatomy.—An arteriovenous communication may be established between the cavernous sinus and the internal carotid artery, giving rise to a pulsating tumour

FIG. 670.—The sinuses at the base of the skull.

in the orbit. Such communication may be the result of a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation. The symptoms are sudden noise and pain in the head, followed by exophthalmos, swelling and congestion of the eyelids and conjunctivæ, and development of a pulsating tumour at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the intercavernous sinuses; or the arterial blood may find its way through the emissary veins (p. 686) into the pterygoid plexus, and thence into the veins of the face. Pulsating tumours of the orbit may also be due to traumatic aneurysm of one of the orbital arteries, and symptoms resembling those of pulsating tumour may be produced by the pressure of an aneurysm of the internal carotid artery upon the ophthalmic veins as they enter the sinus. Ligature

of the internal or common carotid artery has been performed in these cases with considerable success.

It is now well known that caries in the upper parts of the nasal cavities and suppuration in certain of the accessory sinuses of the nose are frequently responsible for septic thrombosis of the cavernous sinuses, in exactly the same way as thrombosis of the transverse sinus is due to septic disease in the mastoid process. Many deaths from meningitis, hitherto unaccounted for, are in reality due to the spread of an infection from the ethmoidal or sphenoidal air-cells to the cavernous sinuses, and thence to the meninges.

The *ophthalmic veins* (fig. 672), two in number, superior and inferior, are devoid of valves.

The *superior ophthalmic vein* begins at the inner angle of the orbit in the *nasofrontal vein* which communicates anteriorly with the angular vein (p. 673). It runs alongside the ophthalmic artery, receives tributaries corresponding to the branches of that vessel, passes between the two heads of the *Rectus lateralis* and through the medial part of the superior orbital fissure, and ends in the cavernous sinus.

The *inferior ophthalmic vein* begins in a venous network at the fore part of the floor and medial wall of the orbit; it receives some veins from the *Rectus inferior*, *Obliquus inferior*, lacrimal sac and eyelids, runs backwards in the lower part of the orbit and divides into two branches. One of these passes

FIG. 671.—Oblique section through the left cavernous sinus. Viewed from behind.

FIG. 672.—Veins of orbit. (Poirier and Charpy.)

through the inferior orbital fissure and joins the pterygoid venous plexus, while the other enters the cranium through the superior orbital fissure and ends in the cavernous sinus, either by a separate opening, or more frequently in common with the superior ophthalmic vein.

The *intercavernous sinuses* (fig. 670) are two in number, an anterior and a posterior, and connect the cavernous sinuses across the middle line. The *anterior*, usually the larger, passes in front of the diaphragma sellæ, the *posterior*

behind it, and they form with the cavernous sinuses a venous circle (*circular sinus*); one or other intercavernous sinus is occasionally absent.

The **superior petrosal sinus** (fig. 670), small and narrow, connects the cavernous with the transverse sinus. It runs lateralwards and backwards, from the posterior end of the cavernous sinus, over the trigeminal nerve, and lies in the attached margin of the tentorium cerebelli and in the superior petrosal sulcus of the temporal bone; it joins the transverse sinus where the latter curves downwards on the inner surface of the mastoid part of the temporal bone. It receives some cerebellar and inferior cerebral veins, and veins from the tympanic cavity.

The **inferior petrosal sinus** (fig. 670) begins in the postero-inferior part of the cavernous sinus, runs backwards in a groove between the petrous part of the temporal bone and the basilar part of the occipital bone, and, passing through the anterior part of the jugular foramen, ends in the superior bulb of the internal jugular vein. It receives the internal auditory veins and also veins from the medulla oblongata, pons, and under surface of the cerebellum.

The relations of the structures transmitted through the jugular foramen are as follows: the inferior petrosal sinus lies medially and anteriorly with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downwards and backwards; the transverse sinus is situated at the lateral and posterior part of the foramen with a meningeal branch of the occipital artery; between the two sinuses are the glossopharyngeal, vagus, and accessory nerves. These three sets of structures are divided from each other by two processes of the dura mater. The junction of the inferior petrosal sinus with the internal jugular vein takes place on the lateral aspect of the nerves.

The **basilar plexus** (fig. 670) consists of several interlacing venous channels between the layers of the dura mater over the basilar part of the occipital bone; it connects the two inferior petrosal sinuses, and communicates with the anterior internal vertebral venous plexus.

Middle meningeal veins.—The middle meningeal veins accompany the branches of the middle meningeal arteries, but, like the cranial blood-sinuses, they consist of channels in the dura mater and their walls are devoid of muscular tissue. They should therefore be termed the *middle meningeal sinuses*.

They communicate above with the superior sagittal sinus and adjoining venous lacunæ, and unite to form two principal trunks, an anterior and a posterior, which accompany more or less closely the branches of the middle meningeal arteries in the grooves on the inner surface of the parietal bone; sometimes they occupy grooves apart from the arteries.* Their mode of ending is subject to some variation. The two trunks may leave the cranial cavity through the foramen spinosum and open into the pterygoid venous plexus, or may join to form a single vessel before passing through the foramen. The anterior trunk may reach the pterygoid plexus by emerging through the foramen ovale, or it may end in the sphenoparietal sinus or in the cavernous sinus. Besides their meningeal tributaries they receive some small inferior cerebral veins, and communicate with the diploic veins and with the middle cerebral vein.

Emissary veins.—The emissary veins pass through apertures in the cranial wall and establish communications between the venous sinuses inside the skull and the veins external to it. Some are always present, others occasionally so. The principal emissary veins are the following. 1. A mastoid vein runs through the mastoid foramen and unites the transverse sinus with the posterior auricular or occipital vein. 2. A parietal vein passes through the parietal foramen and connects the superior sagittal sinus with the veins of the scalp. 3. A network of minute veins (rete canalis hypoglossi) traverses the hypoglossal canal and joins the transverse

* Wood Jones (*Journal of Anatomy and Physiology*, vol. xlv.) has pointed out that the grooves on the inner surfaces of the parietal bones are in reality impressed by the middle meningeal sinuses and not by the middle meningeal arteries, and says 'that, contrary to the general belief of surgeons, the vascular tunnel at the pterion, although it lodges arterial branches, is typically formed by, and typically lodges a venous sinus.' He finds that veins do not commonly pass out of the skull through the foramen spinosum, but adds that the limited number of his dissections for determining this point does not warrant any dogmatic statement. He is inclined to think that the blood which is poured out in most cases of middle meningeal hæmorrhage may be derived from the easily torn sinuses. A similar view is expressed in Poirier and Charpy's *Traité of Human Anatomy*, vol. ii. part 3, p. 930.

sinus with the vertebral vein and deep veins of the neck. 4. An inconstant condyloid vein passes through the condyloid canal and connects the transverse sinus with the deep veins of the neck. 5. A network of veins (*rete foraminis ovalis*) unites the cavernous sinus with the pterygoid plexus through the foramen ovale. 6. Two or three small veins run through the foramen lacerum and connect the cavernous sinus with the pterygoid plexus. 7. A vein traverses the foramen of Vesalius and connects the same parts. 8. An internal carotid plexus of veins accompanies the internal carotid artery through the carotid canal of the temporal bone and unites the cavernous sinus with the internal jugular vein. 9. A vein passes through the foramen cæcum and connects the veins of the nasal cavity with the superior sagittal sinus.

Applied Anatomy.—These emissary veins are of importance in surgery. Inflammatory processes commencing on the outside of the skull may travel inwards through them, and lead to osteophlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of wounds of the scalp.

By means of these emissary veins blood may be abstracted from the intracranial circulation—e.g. leeches applied behind the ear drain blood from the transverse sinus through the mastoid vein. Again, epistaxis in children may relieve severe headache, the blood which flows from the nose being partly derived from the superior sagittal sinus by means of the vein passing through the foramen cæcum.

VEINS OF THE UPPER EXTREMITY AND THORAX

The veins of the upper extremity are divided into two sets, *superficial* and *deep*, which anastomose frequently with each other. The superficial veins are placed beneath the skin, in the superficial fascia; the deep veins accompany the arteries. Both sets are provided with valves, which are more numerous in the deep than in the superficial veins.

SUPERFICIAL VEINS OF UPPER EXTREMITY

The *superficial veins* of the upper extremity are the cephalic, basilic, and median antibrachial veins, and their tributaries.

The *dorsal digital veins* pass along the sides of the fingers and are joined to one another by oblique communicating branches. Those from the adjacent sides of the fingers unite to form three *dorsal metacarpal veins* (fig. 673), which end in a *dorsal venous network* opposite the middle of the metacarpus. The radial part of the network is joined by the dorsal digital vein from the radial side of the index finger and by the dorsal digital veins of the thumb, and is prolonged upwards as the cephalic vein. The ulnar part of the network receives the dorsal digital vein of the ulnar side of the little finger and is continued upwards as the basilic vein. A communicating branch frequently connects the dorsal venous network with the cephalic vein about the middle of the forearm.

The *proper volar digital veins* are connected to the dorsal digital veins by oblique *intercapitular veins* which pass backwards between the heads of the metacarpal bones. They also drain into a venous plexus which is situated over the thenar and hypothenar eminences and across the front of the palm.

The *cephalic vein* (fig. 674) begins in the radial part of the dorsal venous network of the hand and winds upwards round the radial border of the forearm to its volar surface, receiving tributaries from both surfaces. Below the front of the elbow it gives off the *median cubital vein* (median basilic vein), which receives a communicating branch from the deep veins of the forearm and passes medialwards to join the basilic vein. The cephalic vein then ascends in front of the elbow in the groove between the Brachioradialis and the Biceps brachii. It crosses superficially to the musculocutaneous nerve and runs upwards along the lateral border of the Biceps brachii. In the upper third of the arm it passes between the Pectoralis major and Deltoideus, where it is accompanied by the deltoid branch of the thoraco-acromial artery. It pierces the coracoclavicular fascia, crosses the axillary artery, and ends in the axillary vein just below the

clavicle. Sometimes it communicates with the external jugular vein by a branch which ascends in front of the clavicle.

In some cases the median cubital vein is large and carries all or most of the blood from the cephalic into the basilic vein, the result being that the proximal half of the cephalic vein is either absent or of small size.

The *accessory cephalic vein* arises from a small tributary plexus on the back of the forearm or from the ulnar side of the dorsal venous network; it joins

FIG. 673. --The veins on the dorsum of the hand. (Bourguery.)

the cephalic below the elbow. In some cases it springs from the cephalic vein above the wrist and joins it again higher up. A large oblique branch frequently connects the basilic and cephalic veins on the back of the forearm.

The *basilic vein* (fig. 674) begins in the ulnar part of the dorsal venous network of the hand. It runs up for some distance on the posterior surface of the ulnar side of the forearm but inclines forward to the anterior surface below the elbow. It is joined by the median cubital vein, and ascends obliquely in the groove between the Biceps brachii and Pronator teres; filaments of the medial antibrachial cutaneous nerve pass both in front of and behind this portion of the vein. It then runs upwards along the medial border of the Biceps brachii, perforates the deep fascia a little below the middle of the arm,

and, ascending on the medial side of the brachial artery to the lower border of the *Teres major*, is continued onwards as the axillary vein.

The median antibrachial vein drains the venous plexus on the volar surface of the hand. It ascends on the front of the forearm and ends in the basilic or median cubital vein; in a small proportion of cases it divides below the elbow into two branches, one of which joins the basilic, the other the cephalic.

FIG. 674.—The superficial veins of the upper extremity.

Applied Anatomy.—*Venesec-tion* is generally performed at the bend of the elbow, and as a matter of practice the largest vein in this situation, the median cubital (median basilic), is commonly selected. The advantages of selecting this vein are, that in addition to its being the largest vessel and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the *lacertus fibrosus* (bicipital fascia) on which it rests. The disadvantage is, that it is in close relationship with the brachial artery, separated only by the *lacertus fibrosus*; formerly, when venesection was frequently practised, arteriovenous aneurysm was no uncommon result.

Intravenous infusion of normal saline solution is frequently required in modern surgery for conditions of severe shock and after profuse hemorrhages, and has superseded the older method of transfusion of blood. The patient's arm is surrounded by a tight bandage so as to impede the venous return, and a small incision is made over the largest vein visible in front of the elbow; a double ligature is now passed around the vein, and the lower one is tied; the vein is then opened and a cannula, connected with a funnel by tubing, is inserted. The bandage is next removed from the arm, and two, three, or more pints of hot saline solution are allowed to flow into the vein; when a sufficient quantity has gone in, the upper ligature round the vein is tied and a stitch put in the skin wound.

DEEP VEINS OF UPPER EXTREMITY

The deep veins follow the course of the arteries, and form their *venae comitantes*. They are generally arranged in pairs, and are

situated one on either side of the corresponding artery, and connected at intervals by short transverse branches.

Deep veins of the hand.—The superficial and deep volar arterial arches are each accompanied by a pair of venæ comitantes which constitute respectively the *superficial* and *deep volar venous arches*, and receive the veins corresponding to the branches of the arterial arches; thus the *common volar digital veins*, formed by the union of the *proper volar digital veins*, open into the superficial, and the *volar metacarpal veins* into the deep volar venous arches. The deep veins accompanying the dorsal metacarpal arteries receive perforating branches from the volar metacarpal veins, and end in the radial veins and in the dorsal venous network.

The deep veins of the forearm are the venæ comitantes of the radial and ulnar veins and constitute respectively the upward continuations of the deep and superficial volar venous arches; they unite in front of the elbow to form the brachial veins. The radial veins are smaller than the ulnar, and receive the deep veins of the dorsum of the hand. The ulnar veins receive tributaries from the deep volar venous arches and communicate with the superficial veins at the wrist; near the elbow they receive the volar and dorsal interosseous veins and send a large communicating branch (*profunda vein*) to the median cubital vein.

The brachial veins are placed one on either side of the brachial artery, and receive tributaries corresponding with the branches of that artery; near the lower margin of the Subscapularis, they join the axillary vein; the medial one frequently joins the basilic vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The axillary vein begins at the lower border of the Teres major, as the continuation of the basilic vein, increases in size as it ascends, and ends at the outer border of the first rib as the subclavian vein. Near the lower border of the Subscapularis it receives the brachial veins and, close to its termination, the cephalic vein; its other tributaries correspond with the branches of the axillary artery. It lies on the medial side of the axillary artery, which it partly overlaps; between the two vessels are the medial cord of the brachial plexus, the ulnar and the medial anterior thoracic nerves. It is provided with a pair of valves opposite the lower border of the Subscapularis; valves are also found at the ends of the cephalic and subscapular veins.

Applied Anatomy.—Since the axillary vein is superficial to and larger than the axillary artery, which it overlaps, it is more liable to be wounded than the artery in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to it. When it is wounded, there is always a danger of air being drawn into it, and death resulting. To avoid wounding it in extirpating the axillary glands, it is advisable to expose the vein as soon as possible; no sharp cutting instruments should be used after the axillary cavity has been freely exposed; and care should be taken to use no undue force in isolating the glands (p. 613). Should the vein be so imbedded in a malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done after the vessel has been ligatured above and below.

The subclavian vein, the continuation of the axillary vein, extends from the outer border of the first rib to the sternal end of the clavicle, where it unites with the internal jugular vein to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius; behind and above, with the subclavian artery, from which it is separated medially by the Scalenus anterior and the phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. It is usually provided with a pair of valves, which are situated about 2.5 cm. from its termination.

Its tributaries are the external jugular vein, sometimes the anterior jugular vein, and occasionally a small branch, which ascends in front of the clavicle, from the cephalic vein.

At its angle of junction with the internal jugular vein, the left subclavian vein receives the thoracic duct, and the right subclavian vein the right lymphatic duct.

VEINS OF THE THORAX (fig. 675)

The **innominate veins** are two large trunks, placed one on either side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side; they are devoid of valves.

The **right innominate vein**, about 2.5 cm. long, begins behind the sternal end of the right clavicle, and, passing almost vertically downwards, joins the left innominate vein behind the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies in front and to the right of the innominate artery; on its right side are the right phrenic nerve and the right pleura, which are interposed between it and the apex of the lung; behind and to its left is the right vagus nerve.

Its tributaries are the right vertebral, the right internal mammary and the right inferior thyroid veins, and sometimes the first right intercostal vein.

The **left innominate vein**, about 6 cm. long, begins behind the sternal end of the left clavicle and runs obliquely downwards and to the right behind the upper half of the manubrium sterni to the sternal end of the first right costal cartilage, where it unites with the right innominate vein to form the superior vena cava. It is separated from the manubrium sterni by the Sternohyoideus and Sternothyroideus, the thymus or its remains, and some loose areolar tissue. Behind it are the innominate, left common carotid, and left subclavian arteries, together with the left vagus and phrenic nerves. The left innominate vein may occupy a higher level, crossing the jugular notch and lying directly in front of the trachea.

Its tributaries are the left vertebral, left internal mammary, left inferior thyroid, and left superior intercostal veins, sometimes the first left intercostal vein and occasionally some thymic and pericardial vein.

Peculiarities.—Sometimes the innominate veins open separately into the right atrium; in such cases the right vein takes the ordinary course of the superior vena cava; the left vein—*left superior vena cava*, as it is then termed—which may communicate by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, ends in the right atrium. This occasional condition in the adult is due to the persistence of the early fetal condition, and is the normal state of things in birds and some mammals.

The **internal mammary veins** are *venæ comitantes* to the lower half of the internal mammary artery, and receive tributaries corresponding to the branches of the artery. They unite to form a single trunk, which runs up on the medial side of the artery and ends in the corresponding innominate vein. The *superior phrenic vein* (i.e. the vein accompanying the pericardiophrenic artery) usually opens into the internal mammary vein.

The **inferior thyroid veins**, two or more in number, arise in the thyroid gland in a venous network which communicates with the middle and superior thyroid veins. They form a plexus in front of the trachea, behind the Sternothyroideus. From this plexus a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downwards and to the right across the innominate artery to open into the right innominate vein, at its junction with the superior vena cava; frequently the right and left veins open by a common trunk in the latter situation. These veins receive œsophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their terminations.

The **left superior intercostal vein** receives the second and third (and sometimes the fourth) left intercostal veins; it runs obliquely upwards and forwards on the left side of the aortic arch between the left phrenic and vagus nerves and opens into the left innominate vein. It usually receives the left bronchial veins, and sometimes the left superior phrenic vein; it communicates below with the accessory hemiazygos vein.

The **superior vena cava** drains the blood from the upper half of the body. It measures about 7 cm. in length, is formed by the junction of the two innominate veins, and is devoid of valves. It begins behind the cartilage of the right first rib close to the sternum, and, descending vertically behind the first and second intercostal spaces, ends in the upper part of the right atrium opposite the upper border of the third right costal cartilage; the lower half of the

vessel is within the pericardium. In its course it describes a slight curve, the convexity of which is to the right side.

FIG. 675.—The venæ cavæ and the azygos vein, with their tributaries.

Relations.—In front of the superior vena cava are the anterior margins of the right lung and pleura with the pericardium intervening below; these separate it

from the first and second intercostal spaces, and from the second and third right costal cartilages; *behind* it are the root of the right lung and the right vagus nerve. On its *right side* are the phrenic nerve and right pleura; on its *left side*, the commencement of the innominate artery and the ascending aorta, the latter overlapping it. The portion contained within the pericardium is covered, in front and laterally, by the serous pericardium.

Tributaries.—Before it pierces the pericardium, the superior vena cava receives the azygos vein and several small veins from the pericardium and other contents of the mediastinal cavity.

The **azygos vein** begins opposite the first or second lumbar vertebra, as a branch of the right ascending lumbar vein (p. 702); sometimes as a branch of the right renal vein, or of the inferior vena cava. It enters the thorax through the aortic hiatus in the Diaphragm, and ascends along the right side of the vertebral column to the fourth thoracic vertebra, where it arches forward over the root of the right lung, and ends in the superior vena cava, just before that vessel pierces the pericardium. In the aortic hiatus it lies with the thoracic duct on the right side of the aorta; in the thorax it lies upon the intercostal arteries, on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives the right subcostal and intercostal veins with the exception of the vein from the first intercostal space; the veins from the second, third and fourth intercostal spaces open by a common stem called the right superior intercostal vein. It also receives the hemiazygos and accessory hemiazygos veins, several oesophageal, mediastinal, and pericardial veins, and, near its termination, the right bronchial veins. A few imperfect valves are found in the azygos vein; but its tributaries are provided with complete valves.

The **hemiazygos vein** begins in the left ascending lumbar vein or in the left renal vein. It enters the thorax through the left crus of the Diaphragm, and, ascending on the left side of the vertebral column as high as the eighth thoracic vertebra, passes across the column, behind the aorta, oesophagus, and thoracic duct, to end in the azygos vein. It receives the lower three intercostal veins and the subcostal vein of the left side, and some oesophageal and mediastinal veins.

The **accessory hemiazygos vein** descends on the left side of the vertebral column. It receives the veins from the fourth (or fifth) to the eighth intercostal spaces inclusive, and sometimes the left bronchial veins. It crosses the body of the seventh thoracic vertebra and joins the azygos vein.

The **intercostal veins** are sometimes named the *posterior intercostal veins* to distinguish them from the small *anterior intercostal veins* which are tributaries of the musculophrenic and internal mammary veins. They run alongside the anterior rami of the intercostal arteries and are eleven in number on either side. As they approach the vertebral column each receives a tributary corresponding with the posterior ramus of an intercostal artery, and returning blood from the muscles and skin of the back and from the vertebral venous plexuses.

On *both* sides of the thorax the first intercostal vein ascends in front of the neck of the first rib and ends in the corresponding innominate or vertebral vein.

On the right side the second, third and fourth intercostal veins unite to form the *right superior intercostal vein*, which joins the terminal part of the azygos vein. The veins from the intercostal spaces below the fourth open separately into the vena azygos.

On the left side the second and third (and sometimes the fourth) intercostal veins unite to form the left superior intercostal vein (p. 691). The veins from the fourth (or fifth) to the eighth intercostal spaces inclusive end in the accessory hemiazygos vein, and the veins from the lower three spaces in the hemiazygos vein.

Applied Anatomy.—In obstruction of the superior vena cava, the azygos and hemiazygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior vena cavae, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.

Thrombosis of the superior vena cava is oftenest due to pressure exerted on the vessel by an aneurysm or a tumour; it may also occur by propagation of clotting from a tributary peripheral vein. If occlusion of the vessel take place slowly, a collateral venous circulation may be established; the patient will have some cedema with dilation and

congestion of the veins about the head and neck, and may also suffer from attacks of dyspnoea and recurrent pleural effusion. In most cases, however, the blockage of the superior cava takes place rapidly, and is rapidly fatal.

The **bronchial veins**, usually two on either side, return the blood from the larger bronchi, and from the structures at the roots of the lungs; those of the right side open into the terminal part of the vena azygos; those of the left side, into the left superior intercostal vein or the accessory hemiazygos vein. Some of the blood carried to the lungs through the bronchial arteries is returned to the heart through the pulmonary veins.

VEINS OF THE VERTEBRAL COLUMN (figs. 676, 677)

The veins which drain the blood from the vertebral column, the neighbouring muscles, and the meninges of the medulla spinalis form intricate plexuses extending along the entire length of the column; these plexuses are divisible into two groups, external and internal, according to their positions outside or inside the vertebral canal. The plexuses of the two groups anastomose freely with each other, and end in the intervertebral veins.

The **external vertebral venous plexuses**, best marked in the cervical region, consist of anterior and posterior plexuses which anastomose freely with each other.

FIG. 676.—Transverse section of a thoracic vertebra, showing the vertebral venous plexuses.

The **anterior external plexuses** lie in front of the bodies of the vertebrae, communicate with the basivertebral and intervertebral veins, and receive tributaries from the vertebral bodies. The **posterior external plexuses** are placed partly on the posterior surfaces of the vertebral arches and their processes, and partly between the deep dorsal muscles. In the cervical region they anastomose with the vertebral, occipital, and deep cervical veins.

The **internal vertebral venous plexuses** lie within the vertebral canal between the dura mater and the vertebrae, and receive tributaries from the bones and from the medulla spinalis. They form a closer network than the external plexuses, and, running mainly in a vertical direction, form four longitudinal veins, two

in front and two behind; they therefore may be divided into anterior and posterior groups. The **anterior internal plexuses** consist of large veins which lie on the posterior surfaces of the vertebral bodies and intervertebral fibrocartilages, on either side of the posterior longitudinal ligament; under cover of this ligament they are connected by transverse branches into which the basivertebral veins open. The **posterior internal plexuses** are placed one on either side of the middle line in front of the vertebral arches and ligamenta flava, and anastomose, by veins passing through those ligaments, with the posterior external plexuses.

The anterior and posterior plexuses communicate freely with one another by a series of venous rings, one opposite each vertebra. Around the foramen magnum they form an intricate network which opens into the vertebral veins and is connected above with the occipital sinus, the basilar plexus, the condyloid emissary vein, and the rete canalis hypoglossi.

The **basivertebral veins** emerge from the foramina on the posterior surfaces of the vertebral bodies. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of

the cranial bones. They communicate through small openings on the front and sides of the bodies of the vertebræ with the anterior external vertebral plexuses, and converge behind to form single (sometimes double) veins which open by valved orifices into the transverse branches uniting the anterior internal vertebral plexuses. The basivertebral veins become greatly enlarged in advanced age.

FIG. 677.—Median sagittal section of two thoracic vertebræ, showing the vertebral venous plexuses.

The **intervertebral veins** accompany the spinal nerves through the intervertebral foramina; they receive the veins from the medulla spinalis, drain the internal and external vertebral plexuses and end in the vertebral, intercostal, lumbar, and lateral sacral veins, their orifices being provided with valves.

The **veins of the medulla spinalis** are situated in the pia mater and form a tortuous, venous plexus. In this plexus there are: (1) two median longitudinal veins, one in front of the anterior fissure, and the other behind the posterior sulcus of the medulla spinalis; and (2) four lateral longitudinal veins which run behind the nerve-roots. They end in the internal vertebral venous plexuses. Near the base of the skull they unite to form two or three small trunks, which communicate with the vertebral veins, and end in the inferior cerebellar veins, or in the inferior petrosal sinuses.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS

The veins of the lower extremity are subdivided, like those of the upper extremity, into two sets, superficial and deep: the superficial veins are placed beneath the skin in the superficial fascia; the deep veins accompany the arteries. Both sets are provided with valves, which are more numerous in the deep than in the superficial set. Valves are more numerous in the veins of the lower than in those of the upper extremity.

1. SUPERFICIAL VEINS OF LOWER EXTREMITY

The **superficial veins** of the lower extremity are the great and small saphenous veins and their tributaries.

The **dorsal digital veins** receive, in the clefts between the toes, the *intercapitular veins* from the plantar digital veins, and then join to form *dorsal metatarsal veins*, which unite across the distal ends of the metatarsal bones in a *dorsal venous arch*. Proximal to this arch is an irregular venous network which receives tributaries from the deep veins and is joined at the sides of the foot by a *medial* and a *lateral marginal vein*, formed mainly by the union of veins from the superficial parts of the sole of the foot.

On the sole of the foot the superficial veins form a *plantar cutaneous venous arch*, which extends across the roots of the toes and opens at the sides of the foot into the medial and lateral marginal veins. Proximal to this arch is a *plantar cutaneous venous network* which is especially dense in the fat beneath the heel; this network communicates with the plantar cutaneous venous arch and with the deep veins, but is chiefly drained into the medial and lateral marginal veins.

The **great saphenous vein** (fig. 678), the longest vein in the body, begins in the medial marginal vein of the foot and ends in the femoral vein about 3 cm. below the inguinal ligament. It ascends in front of the tibial malleolus and along the medial side of the leg in relation with the saphenous nerve. It

runs upwards behind the medial condyles of the tibia and femur and along the medial side of the thigh and, passing through the fossa ovalis, ends in the femoral vein. The valves in the great saphenous vein vary from ten to twenty in number; they are more numerous in the leg than in the thigh.

FIG. 678.—The great saphenous vein and its tributaries.

Tributaries.—At the ankle it receives veins from the sole of the foot through the medial marginal vein; in the leg it communicates freely with the small saphenous vein and with the anterior and posterior tibial veins, and receives many cutaneous veins; in the thigh it communicates with the femoral vein and receives numerous tributaries; those from the medial and posterior parts of the thigh frequently unite to form a large *accessory saphenous vein* which joins the main vein at a variable level. Near the fossa ovalis (fig. 679) it is joined by the superficial epigastric, superficial iliac circumflex, and superficial external pudendal veins. The superficial epigastric and superficial iliac circumflex veins drain the lower part of the abdominal wall, the latter vein also receiving tributaries from the upper and lateral parts of the thigh; the superficial external pudendal vein drains part of the scrotum and receives the superficial dorsal vein of the penis.

A vein, named the *thoraco-epigastric*, runs along the lateral wall of the trunk, connecting the superficial epigastric with the lateral thoracic veins and thus establishing an important communication between the femoral and axillary veins.

The *small saphenous vein* (fig. 680) begins behind the lateral malleolus as a continuation of the lateral marginal vein; it first ascends along the lateral margin of the tendo calcaneus, and then crosses it obliquely to reach the middle of the back of the leg. Running upwards, it perforates the deep fascia in the lower part of the popliteal fossa, and ends in the popliteal vein, between the heads of the Gastrocnemius. It communicates with the deep veins on the dorsum of the foot, and receives numerous large tributaries from the back of the leg. Before it pierces the deep fascia, it gives off a branch which runs upwards and forwards to join the great saphenous vein; this branch is sometimes large, and may then form the direct continuation of the small saphenous vein. In the lower third of the leg the vein is in close relation with

the sural nerve, in the upper two-thirds with the medial sural cutaneous nerve.

The small saphenous vein possesses from nine to twelve valves, one of which is found near its termination in the popliteal vein.

Applied Anatomy.—A varicose condition is more frequently met with in the saphenous veins than in the other veins of the body, except perhaps the testicular and hæmorrhoidal veins. The main cause of this is the high blood-pressure, determined chiefly by the erect position; and the length of the column of blood, which has to be propelled in an uphill direction. In normal vessels there is only just sufficient force to perform this task; and in those cases where there is diminished resistance of the walls of the veins, these vessels are liable to dilate and a varicose condition is set up. This diminished resistance may be due to heredity, the vein-walls being congenitally weak, or may follow inflammatory conditions of the vessels. Increased blood-pressure in the veins, caused by any obstacle to the return of the venous blood, such as the pressure of a tumour, or the gravid uterus, or tight gartering, may also produce varix. In the normal condition of the veins, the valves in their interior break up the column of blood into a number of smaller columns,

FIG. 679.—The great saphenous vein and its tributaries at the fossa ovalis.

and so to a considerable extent mitigate the ill effects of the erect position; but when the dilatation of the veins has reached a certain limit, the valves become incapable of supporting the overlying column of blood, and the pressure is increased, tending to emphasise also the varicose condition. Both the saphenous veins in the leg are accompanied by nerves, the great saphenous being joined by its companion nerve just below the level of the knee-joint; no doubt much of the pain of varicose veins in the leg is due to this fact.

Operations for the relief of varicose veins are frequently required, portions of the veins being removed after having been ligatured above and below. It is important to note whether the main varicose area drains into the great or the small saphenous vein—the former condition being much the more common—and to control the venous return by removing a small portion of the main trunk just before it opens into the deep vein by passing through the deep fascia; thus in most cases a piece should be removed from the great saphenous just before it passes through the fossa ovalis (saphenous opening), and in addition the affected veins should be excised just above and below the level of the knee-joint. In other cases the small saphenous will have to be dealt with immediately below the point where it pierces the fascial roof of the popliteal fossa.

DEEP VEINS OF LOWER EXTREMITY

The deep veins of the lower extremity accompany the arteries and their branches; they possess numerous valves.

The plantar digital veins arise from plexuses on the plantar surfaces of the digits, and, after sending *intercapitular veins* to join the dorsal digital veins, unite to form four *plantar metatarsal veins*; these run backwards in the metatarsal spaces, communicate, by means of perforating veins, with the veins on the dorsum of the foot, and unite to form the *deep plantar venous arch* which lies alongside the plantar arterial arch. From the deep plantar venous arch the *medial* and *lateral plantar veins* run backwards close to the corresponding arteries and, after communicating with the great and small saphenous veins, unite behind the medial malleolus to form the posterior tibial veins.

The posterior tibial veins accompany the posterior tibial artery, and are joined by the *peroneal veins*.

The anterior tibial veins are the upward continuations of the *venæ comitantes* of the *dorsalis pedis* artery. They leave the front of the leg by passing between the tibia and fibula, through the upper part of the crural interosseous membrane, and unite with the posterior tibial veins to form the *popliteal vein*.

The popliteal vein, formed by the junction of the anterior and posterior tibial veins at the lower border of the Popliteus, ascends through the popliteal fossa to the aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is medial to the artery; between the heads of the Gastrocnemius it is superficial to it; above the knee-joint, it is lateral to it. Its tributaries are the small saphenous vein and the veins corresponding to the branches of the popliteal artery. There are usually four valves in the popliteal vein.

The femoral vein accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it is lateral to the artery; higher up, it is behind it; at the inguinal ligament, it is medial to it. It receives numerous muscular tributaries, and about 4 cm. below the inguinal ligament is joined by the *vena profunda femoris*; near its termination it is joined by the great saphenous vein. It contains three valves.

The *vena profunda femoris* lies superficial to the corresponding artery; it receives tributaries corresponding to the muscular and perforating branches of the *arteria profunda femoris*, and through these establishes communications with the popliteal vein below and the inferior gluteal vein above. It also receives the medial and lateral femoral circumflex veins.

VEINS OF ABDOMEN AND PELVIS (fig. 681)

The external iliac vein, the upward continuation of the femoral vein, begins behind the inguinal ligament, and ascends along the brim of the lesser pelvis, to a point opposite the sacro-iliac articulation, where it unites with the hypogastric vein to form the common iliac vein. On the right side, it lies at first medial to the artery; but, as it passes upwards, gradually inclines behind it. On the left side, it lies altogether on the medial side of the artery. It frequently contains one, sometimes two, valves.

Tributaries.—It receives the inferior epigastric, deep iliac circumflex, and pubic veins.

FIG. 680.—The small saphenous vein.

The **inferior epigastric vein** is formed by the union of the *venæ comitantes* of the inferior epigastric artery, which communicate above with the superior epigastric vein; it joins the external iliac vein about 1.25 cm. above the inguinal ligament.

The **deep iliac circumflex vein** is formed by the union of the *venæ comitantes* of the deep iliac circumflex artery, and joins the external iliac vein about 2 cm. above the inguinal ligament.

FIG. 681.—The veins of the right half of the male pelvis. (Spalteholz.)

The **pubic vein** communicates with the obturator vein in the obturator foramen, ascends on the back of the os pubis alongside the pubic branch of the inferior epigastric artery and ends in the external iliac vein.

The **hypogastric or internal iliac vein** begins near the upper part of the greater sciatic foramen, ascends behind and slightly medial to the hypogastric artery, and, at the brim of the pelvis, joins with the external iliac vein to form the common iliac vein.

Tributaries.—With the exception of the foetal umbilical vein, which passes upwards and backwards from the umbilicus to the liver, and the ilio-lumbar vein, which usually joins the common iliac vein, the tributaries of the hypogastric vein correspond with the branches of the hypogastric artery. It receives (a) the glutæal, internal pudendal, and obturator veins, which have their origins outside the pelvis;

(b) the lateral sacral veins, which lie in front of the sacrum; and (c) the middle hæmorrhoidal, the vesical, uterine, and vaginal veins, which originate in venous plexuses connected with the pelvic viscera.

1. The **superior gluteal veins** (gluteal veins) are the *venæ comitantes* of the superior gluteal artery; they receive tributaries from the buttock corresponding with the branches of the artery, enter the pelvis through the greater sciatic foramen, above the Piriformis, and end in the hypogastric vein; they frequently unite to form a single trunk before ending in this vein.

2. The **inferior gluteal veins** (sciatic veins) are the *venæ comitantes* of the inferior gluteal artery; they begin on the upper part of the back of the thigh, where they anastomose with the medial femoral circumflex and first perforating veins; they enter the pelvis through the lower part of the greater sciatic foramen and join to form a stem which opens into the lower part of the hypogastric vein.

3. The **internal pudendal veins** (internal pudic veins) are the *venæ comitantes* of the internal pudendal artery. They begin in the deep veins of the penis, which issue from the corpus cavernosum penis, accompany the internal pudendal artery, and unite to form a single vessel, which ends in the hypogastric vein. They receive the veins from the urethral bulb, and the perinæal and inferior hæmorrhoidal veins. The deep dorsal vein of the penis communicates with the internal pudendal veins, but ends mainly in the pudendal plexus.

4. The **obturator vein** begins in the upper portion of the adductor region of the thigh and enters the pelvis through the upper part of the obturator foramen. It runs backwards and upwards on the lateral wall of the pelvis below the obturator artery, passes between the ureter and the hypogastric artery, and ends in the hypogastric vein. Sometimes it is replaced by an enlarged pubic vein (p. 699) which joins the external iliac vein.

5. The **lateral sacral veins** accompany the lateral sacral arteries and end in the hypogastric vein.

6. The **middle hæmorrhoidal vein** varies in size; it begins in the hæmorrhoidal plexus and receives tributaries from the bladder, prostate, and seminal vesicle; it runs lateralwards on the pelvic surface of the Levator ani and ends in the hypogastric vein.

The **hæmorrhoidal plexus** surrounds the rectum, and communicates in front with the vesical plexus in the male, and the uterovaginal plexus in the female. It consists of two parts, an *internal* in the submucosa, and an *external* outside the muscular coat of the rectum. The internal plexus presents a series of dilated pouches which are arranged in a circle around the tube, immediately above the anal orifice, and are connected by transverse branches; it drains mainly into the superior hæmorrhoidal vein.

The lower part of the external plexus is drained by the inferior hæmorrhoidal veins into the internal pudendal vein; the middle part by the middle hæmorrhoidal vein into the hypogastric vein; and the upper part by the superior hæmorrhoidal vein which forms the commencement of the inferior mesenteric vein, a tributary of the portal vein. A free communication between the portal and systemic venous systems is established through the hæmorrhoidal plexus.

The **pudendal plexus** lies behind the arcuate pubic ligament and the lower part of the symphysis pubis, and in front of the bladder and prostate. Its chief tributary is the deep dorsal vein of the penis, but it also receives branches from the front of the bladder and prostate. It communicates with the vesical plexus and with the internal pudendal vein, and drains into the vesical and hypogastric veins. The *prostatic veins* form a well-marked *prostatic plexus* which lies partly in the fascial sheath of the prostate and partly between the sheath and the prostatic capsule. It communicates with the pudendal and vesical plexuses.

The **vesical plexus** envelops the lower part of the bladder and the base of the prostate and communicates with the pudendal and prostatic plexuses. It is drained, by means of several vesical veins, into the hypogastric veins.

Applied Anatomy.—The veins of the hæmorrhoidal plexus are apt to become dilated and varicose, and form piles. This is due to several anatomical reasons: the vessels are contained in very loose connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood-pressure; the condition is favoured by gravitation, being influenced by the erect posture,

either sitting or standing, and by the fact that the superior hæmorrhoidal and portal veins have no valves; the veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defæcation; they are affected by every form of portal obstruction.

The prostatic plexus of veins is apt to become congested in inflammatory conditions in the neighbourhood, such as acute gonorrhœal prostatitis. It is owing to the free communication which exists between this and the middle hæmorrhoidal plexus that great relief can be given by free saline purgation.

Hæmorrhage may be very free from the prostatic plexus after operations on that gland, but can usually be checked by hot fluid irrigation. Septic thrombosis sometimes occurs after operations, and infected emboli may find their way into the general circulation.

The dorsal veins of the penis are two in number, a superficial and a deep. The *superficial dorsal vein* drains the prepuce and skin of the penis, and, running backwards in the subcutaneous tissue, inclines to the right or left, and opens into the corresponding superficial external pudendal vein, a tributary of the great saphenous vein. The *deep dorsal vein* lies within the fibrous envelope of the penis; it receives blood from the glans penis and corpora cavernosa penis, and courses backwards in the middle line between the dorsal arteries; near the root of the penis it passes between the two parts of the suspensory ligament and then through an aperture between the arcuate pubic ligament and the transverse ligament of the pelvis, and divides into two branches, which enter the pudendal plexus. It also communicates below the symphysis pubis with the internal pudendal vein.

The uterine plexuses lie along the sides and superior angles of the uterus between the two layers of the broad ligament, and communicate with the ovarian and vaginal plexuses. They are drained by a pair of uterine veins on either side; these arise from the lower parts of the plexuses, opposite the external orifice of the uterus, and open into the corresponding hypogastric vein.

The vaginal plexuses are placed at the sides of the vagina; they communicate with the uterine, vesical, and hæmorrhoidal plexuses, and are drained by the vaginal veins, one on either side, into the hypogastric veins.

The common iliac veins are formed by the union of the external iliac and hypogastric veins, in front of the sacro-iliac articulation; passing obliquely upwards they end on the right side of the fifth lumbar vertebra by uniting with each other at an acute angle to form the inferior vena cava. The *right common iliac vein*, shorter than the left, is nearly vertical in its direction, and ascends behind, and then lateral to its artery. The *left common iliac vein*, longer and more oblique than the right, is at first situated on the medial side of its artery, and then behind the right common iliac artery. Each common iliac vein receives the iliolumbar, and sometimes the lateral sacral veins; the left vein receives the middle sacral vein. There are no valves in these veins.

The middle sacral veins accompany the corresponding artery along the front of the sacrum, and join to form a single vein, which usually ends in the left common iliac vein, but sometimes in the angle of junction of the two common iliac veins.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses the aorta, and joins the right vein to form the vena cava. In these cases, the two common iliac veins are connected by a small communicating branch at the spot where they are usually united.

The inferior vena cava (fig. 675) conveys the blood from the parts below the Diaphragm to the heart. It is formed by the junction of the two common iliac veins, on the right side of the fifth lumbar vertebra. It ascends in front of the vertebral column, on the right side of the aorta, and, having reached the liver, is contained in a deep groove on its posterior surface. It then perforates the Diaphragm between the median and right portions of its central tendon; it subsequently inclines forwards and medialwards for about 2.5 cm., and, piercing the fibrous pericardium, passes behind the serous pericardium to open into the lower and posterior part of the right atrium. In front of its atrial orifice is a semilunar valve, termed the *valve of the inferior vena cava* (Eustachian valve); this valve is rudimentary in the adult, but is of large size and exercises an important function in the fœtus (p. 566).

Relations.—The *abdominal portion* of the inferior vena cava is in relation in front, from below upwards, with the right common iliac artery, the lower part of the mesentery and its vessels, the right testicular artery, the inferior part of the duodenum, the head of the pancreas, the epiploic foramen, the common bile-duct, the portal vein, the hepatic artery, and the posterior surface of the liver; the last partly overlaps and occasionally completely surrounds it; *behind*, with the vertebral column, the right Psoas major, the right crus of the Diaphragm, the right inferior phrenic, suprarenal, renal and lumbar arteries, right sympathetic trunk and right coeliac ganglion, and the medial part of the right suprarenal gland; on the *right side*, with the right kidney and ureter; on the *left side*, with the aorta, right crus of the Diaphragm, and the caudate lobe of the liver.

The *thoracic portion* is only about 2.5 cm. in length, and is situated partly inside and partly outside the pericardial sac. The *extrapericardial part* is separated from the right pleura and lung by a fibrous band, named the *right phrenicopericardiac ligament*. This ligament, often feebly marked, is attached below to the margin of the vena-caval opening in the Diaphragm and above to the pericardium in front of the root of the right lung. The *intrapericardiac part* is very short and is covered anterolaterally by the serous layer of the pericardium.

Peculiarities.—This vessel is sometimes placed on the left side of the aorta, as high as the left renal vein, and, after receiving this vein, crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, and in such a case the abdominal and the thoracic viscera, together with the great vessels, are all transposed. Occasionally it joins the azygos vein, which is then of large size. In such cases, the superior vena cava receives the whole of the blood from the body, except that from the hepatic veins, which passes directly into the right atrium.

Applied Anatomy.—Thrombosis of the inferior vena cava is due to much the same causes as that of the superior (p. 693). It usually causes oedema of the legs and back, without ascites; if the renal veins are involved, blood and albumin will often appear in the urine. An extensive collateral venous circulation is soon established by enlargement either of the superficial or of the deep veins, or of both. In the first case the epigastric, the iliac circumflex, the lateral thoracic, the internal mammary, the intercostals, the external pudendal, and the lumbovertebral anastomotic veins of Braune effect the communication with the superior cava; in the second, the deep anastomosis is made by the azygos and hemiazygos and the lumbar veins.*

Tributaries.—In addition to the two common iliac veins the inferior vena cava receives the following veins.

Lumbar.	Renal.	Right inferior phrenic.
Right testicular or ovarian.	Right suprarenal.	Hepatic.

The **lumbar veins**, four in number on either side, collect the blood by dorsal tributaries from the muscles and skin of the loins, and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the vertebral column, they receive veins from the vertebral plexuses, and then pass forwards on the sides of the bodies of the vertebræ, beneath the Psoas major, and end in the posterior part of the inferior vena cava. The left lumbar veins are longer than the right, and run behind the aorta. The lumbar veins are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the *ascending lumbar vein*; it forms the most frequent origin of the corresponding azygos or hemiazygos vein, and serves to connect the common iliac, ilio-lumbar, and azygos or hemiazygos veins of its own side of the body.

The **testicular veins** (spermatic veins) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus, called the *pampiniform plexus* which constitutes the greater mass of the spermatic cord and ascends along the cord, in front of the ductus deferens. Below the subcutaneous inguinal ring the veins of the plexus unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the abdominal inguinal ring, coalesce to form two veins, which run upwards in front of the Psoas major and the ureter, behind the peritoneum, lying one on either side of the testicular artery. These two veins

* G. Blumer, in Osler and McCrae's *System of Medicine*, London, 1908, vol. iv.

join to form a single vein, which opens on the right side into the inferior vena cava at an acute angle; on the left side into the left renal vein at a right angle. The testicular veins are provided with valves.* The left vein passes behind the iliac part of the descending colon and the lower margin of the pancreas, the right behind the terminal part of the ilium and the inferior part of the duodenum.

Applied Anatomy.—The testicular veins are very frequently varicose, constituting the condition known as *varicocele*. Though it is quite possible that the originating cause of this affection may be a congenital weakness of the walls of the veins of the pampiniform plexus, it must be admitted that there are anatomical reasons why these veins should become varicose: viz. the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall. Varicocele almost invariably occurs on the left side, and this has been accounted for by the facts that the left testicular vein joins the left renal at a right angle; that it is overlaid by the iliac part of the descending colon, and that when this portion of the gut is full of fecal matter, in cases of constipation, its weight impedes the return of the venous blood; and finally that the left testicular veins are somewhat longer than the right.

The operation for the removal of a varicocele consists in making a small incision just over the subcutaneous inguinal ring; the cord is lifted out and the spermatic fascia incised; the plexus of veins is then isolated from the ductus deferens and ligatured above and below, as high and as low as possible, and the intermediate portion cut away: the divided ends are fixed together with a suture, and the skin wound closed. The venous return is subsequently carried out by the small veins of the ductus deferens, of the Cremaster and those connecting with the scrotal tissues. In removing a varicocele the testicular artery is generally removed at the same time.

The ovarian veins in the female correspond with the testicular veins in the male; each forms a plexus between the layers of the broad ligament near the ovary and uterine tube, and communicates with the uterine plexus. Two veins issue from this plexus and ascend in front of the external iliac artery, one lying on either side of the ovarian. Their further course and their mode of termination are the same as those of the testicular veins. Valves are occasionally found in the ovarian veins. Like the uterine veins, they become much enlarged during pregnancy.

The renal veins are of large size, and are placed in front of the renal arteries. The left is thrice the length of the right (7.5 cm. to 2.5 cm.), and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left testicular (or ovarian) and one of the left inferior phrenic veins, and, generally, the left suprarenal vein. It opens into the inferior vena cava at a slightly higher level than the right.

The suprarenal veins are two in number: the right ends in the inferior vena cava; the left usually in the left renal.

The inferior phrenic veins follow the course of the inferior phrenic arteries on the Diaphragm; the right ends in the inferior vena cava; the left is often represented by two branches, one of which ends in the left renal or suprarenal vein, while the other passes in front of the oesophageal hiatus in the Diaphragm and opens into the inferior vena cava.

The hepatic veins drain the liver, and commence in the *intra-lobular veins* which receive the blood from the sinusoids of the liver lobules. The intra-lobular veins open into the *sublobular veins*, and these in turn unite to form the hepatic veins which open into that portion of the inferior vena cava which lies in the groove on the posterior surface of the liver. The hepatic veins are arranged in two groups, upper and lower. The *upper group* usually consists of three large veins; those of the *lower group* vary in number, are of small size and come from the right and caudate lobes. The hepatic veins are in direct contact with the hepatic tissue and are destitute of valves.

* Rivington has pointed out that valves are usually found at the orifices of both the right and left testicular veins. When, however, valves are not found at the opening of the left vein into the left renal vein, they are generally present in the left renal vein within 6 mm. from the orifice of the testicular vein.—*Journal of Anatomy and Physiology*, vol. vii. p. 163.

PORTAL SYSTEM OF VEINS (fig. 682)

The portal system includes all the veins which drain the blood from the abdominal part of the digestive tube (with the exception of the lower part of the rectum) and from the spleen, pancreas, and gall bladder. From these viscera the blood is conveyed to the liver by the *portal vein*. In the liver this vein ramifies like an artery and ends in capillary-like vessels termed sinusoids, from which the blood is conveyed to the inferior vena cava by the hepatic

FIG. 682.—Portal vein and its tributaries.

veins. The blood of the portal system therefore passes through two sets of minute vessels, viz. (a) the capillaries of the digestive tube, spleen, pancreas, and gall bladder; and (b) the sinusoids of the liver. In the adult the portal vein and its tributaries are destitute of valves; in the foetus and for a short time after birth valves can be demonstrated in the tributaries of the portal vein; ~~as a~~ rule they atrophy and disappear, but sometimes persist in a degenerate form.

The portal vein is about 8 cm. long, and is formed at the level of the second lumbar vertebra by the junction of the superior mesenteric and hepatic

(splenic) veins, the union of these veins taking place in front of the inferior vena cava and behind the neck of the pancreas. It passes upwards behind the superior part of the duodenum, and then ascends in the right border of the lesser omentum to the right extremity of the porta hepatis (transverse fissure of the liver), where it divides into a right and a left branch, which accompany the corresponding branches of the hepatic artery into the substance of the liver. In the lesser omentum it is placed behind and between the common bile duct and the hepatic artery, the former lying to the right of the latter; it is surrounded by the hepatic plexus of nerves, and is accompanied by numerous lymphatic vessels and some lymph-glands. The *right branch* of the portal vein enters the right lobe of the liver, but before doing so generally receives the cystic vein. The *left branch*, longer but of smaller calibre than the right, crosses the left sagittal fossa (longitudinal fissure), gives branches to the caudate lobe, and then enters the left lobe of the liver. As it crosses the left sagittal fossa it is joined in front by a fibrous cord, the *ligamentum teres* or *obliterated umbilical vein*, and is united to the inferior vena cava by a second fibrous cord, the *ligamentum venosum* or *obliterated ductus venosus*.

The tributaries of the porta vein are :

- | | |
|-------------------------|-------------------|
| 1. Lienal (Splenic). | 4. Right gastric. |
| 2. Superior mesenteric. | 5. Cystic. |
| 3. Coronary. | 6. Parumbilical. |

1. The **lienal or splenic vein** is of large size, but is not tortuous like the artery; it commences by five or six branches which return the blood from the spleen. These unite to form a single vessel, which passes from left to right, grooving the upper part of the posterior surface of the pancreas, below the lienal artery, and ends behind the neck of the pancreas by uniting at a right angle with the superior mesenteric vein, to form the portal vein.

Tributaries.—It receives the short gastric veins, the left gastro-epiploic vein, the pancreatic veins, and the inferior mesenteric vein.

(a) The **short gastric veins**, four or five in number, drain the fundus and left part of the greater curvature of the stomach, and pass between the two layers of the gastrolial ligament to end in the lienal vein or in one of its large tributaries.

(b) The **left gastro-epiploic vein** receives branches from the surfaces of the stomach and from the greater omentum; it runs from right to left along the greater curvature of the stomach and ends in the commencement of the lienal vein.

(c) The **pancreatic veins** are several small vessels which drain the body and tail of the pancreas.

(d) The **inferior mesenteric vein** returns blood from the rectum, and from the sigmoid and descending parts of the colon. It begins in the rectum as the *superior hæmorrhoidal vein*, which has its origin in the hæmorrhoidal plexus (p. 700), and through this plexus communicates with the middle and inferior hæmorrhoidal veins. The superior hæmorrhoidal vein leaves the lesser pelvis, crosses the left common iliac vessels with the superior hæmorrhoidal artery, and is continued upwards as the inferior mesenteric vein. This vein lies to the left of its artery and ascends behind the peritoneum and in front of the left Psoas major; it then passes behind the body of the pancreas and opens into the lienal vein; sometimes it ends in the angle of union of the lienal and superior mesenteric veins.

Tributaries.—The inferior mesenteric vein receives the sigmoid veins from the sigmoid colon, and the left colic vein from the descending colon and left colic flexure.

2. The **superior mesenteric vein** returns the blood from the small intestine, from the cæcum, and from the ascending and transverse portions of the colon. It begins in the right iliac fossa by the union of the veins which drain the terminal part of the ileum, the cæcum and vermiform process. It ascends between the two layers of the mesentery on the right side of the superior mesenteric artery, and in its upward course passes in front of the right ureter, the inferior vena cava, the inferior part of the duodenum, and the processus uncinatus of the head of the pancreas. Behind the neck of the pancreas it unites with the lienal vein to form the portal vein.

Tributaries.—The superior mesenteric vein receives the veins which correspond with the branches of the superior mesenteric artery, viz. the jejunal, ileal, ileocolic,

right colic, and middle colic veins; it is also joined by the right gastro-epiploic and the pancreaticoduodenal veins.

The **right gastro-epiploic vein** receives branches from the greater omentum and from the lower part of the stomach; it runs from left to right along the greater curvature of the stomach, between the two layers of the greater omentum.

The **pancreaticoduodenal veins** accompany their corresponding arteries; the lower one frequently joins the right gastro-epiploic vein.

3. The **coronary vein** derives tributaries from both surfaces of the stomach: it runs from right to left along the lesser curvature of the stomach between the two layers of the lesser omentum, to the oesophageal opening of the stomach, where it receives some oesophageal veins. It then turns backwards and passes from left to right behind the omental bursa, and ends in the portal vein.

4. The **right gastric vein** (pyloric vein), of small size, runs from left to right along the pyloric portion of the lesser curvature of the stomach between the two layers of the lesser omentum, and ends in the portal vein.

5. The **cystic vein** drains the blood from the gall-bladder; it accompanies the cystic duct, and usually ends in the right branch of the portal vein.

6. **Parumbilical veins.**—In the course of the ligamentum teres of the liver and of the middle umbilical ligament, small veins (parumbilical) are found, which establish an anastomosis between the veins of the anterior abdominal wall and the portal, hypogastric, and iliac veins. The best marked of these small veins is one which begins at the umbilicus and runs backwards and upwards in, or on the surface of, the ligamentum teres between the layers of the falciform ligament, to end in the left portal vein.

Applied Anatomy.—Obstruction to the portal vein may produce ascites, and this may arise from many causes, e.g. (1) the pressure of a tumour on the portal vein, such as cancer or hydatid cyst in the liver, enlarged lymph-glands in the lesser omentum, or cancer of the head of the pancreas; (2) from cirrhosis of the liver, when the radicles of the portal vein are pressed upon by the contracting fibrous tissue in the portal canals; (3) from valvular disease of the heart, and back pressure on the hepatic veins, and so on the whole of the circulation through the liver. In this condition the prognosis as regards life and freedom from ascites may be much improved by the establishment of a good collateral venous circulation to relieve the portal obstruction in the liver. This is effected by communications between (a) the gastric veins, and the oesophageal veins which often project as a varicose bunch into the stomach, emptying themselves into the hemiazygos vein; (b) the veins of the colon and duodenum, and the left renal vein; (c) the accessory portal system of Sappey, branches of which pass in the round and falciform ligaments (particularly the latter) to unite with the epigastric and internal mammary veins, and through the diaphragmatic veins with the azygos; a single large vein, shown to be a parumbilical vein, may pass from the hilum of the liver by the round ligament to the umbilicus, producing there a bunch of prominent varicose veins known as the *caput Medusæ*; (d) the veins of Retzius, which connect the intestinal veins with the inferior vena cava and its retroperitoneal branches; (e) the inferior mesenteric veins, and the hæmorrhoidal veins that open into the hypogastriacs; (f) very rarely the ductus venosus remains patent, affording a direct connexion between the portal vein and the inferior vena cava.

An operation for the relief of portal obstruction on these lines has been advocated by Rutherford Morison and by Talma. It consists in roughening the opposed surfaces of the liver and Diaphragm and stitching them together, so as to secure vascular inflammatory adhesions between the two. The greater omentum may with advantage be interposed between them, so as to increase the amount of the adhesions.

Thrombosis of the portal vein is a very serious event, and is oftenest due to pathological processes causing compression of the vessel or injury to its wall, such as tumours or inflammation about the pylorus or head of the pancreas, or to gall-stones, or cirrhosis of the liver.

Thrombosis of the mesenteric veins produces very acute symptoms, similar to those of embolism of the mesenteric arteries (see p. 639).

Infective emboli lodging in the portal venules give rise to a condition known as *septic* or *suppurative pylephlebitis* or, more shortly, *portal pyæmia*. They occur most often in one of the ileocolic radicles, and are due to appendicitis, but the infection may arise from anywhere in the portal system (e.g. the superior hæmorrhoidal radicles). Fragments of the infected clot break off from the original thrombus and lodge in the smaller veins of the liver, causing the development of multiple abscesses in its substance, and a rapidly fatal result. A similar path of infection is taken by the *entamoeba histolytica* of dysentery, when it passes into the liver and produces *tropical abscess*.

THE LYMPHATIC SYSTEM

The lymphatic system includes the lymphatic vessels and lymph-glands. The lymphatic vessels of the small intestine receive the special designation of *lacteals* or *chyliferous vessels*; they differ in no respect from the lymphatic vessels generally, excepting that during the process of absorption of a fatty meal they contain a milk-white fluid, the *chyle*. In most of the tissues of the body there are also minute spaces and channels which contain lymph; the cells of connective tissue, for example, are bathed in this fluid. As fresh lymph is formed by transudation from the blood-capillaries, that lying in the tissue-spaces is moved on into the lymphatic vessels, which probably commence in every case, as those in the intestinal villi are known to do, by blind extremities.

The **lymphatic vessels** are exceedingly delicate, and their coats are so transparent that the fluid they contain is readily seen through them. They are constricted at intervals and so present a knotted or beaded appearance; these constrictions correspond to the situations of valves in the interior of the vessels. Lymphatic vessels have been found in nearly every texture and organ of the body which contains blood-vessels. Non-vascular structures such as cartilage, nails, cuticle, and hair have none, but with these exceptions it is probable that all parts are permeated by these vessels.

Structure of lymphatic vessels.—The larger lymphatic vessels are each composed of three coats. The *internal* coat is thin, transparent, slightly elastic, and consists

of a layer of elongated endothelial cells supported on an elastic membrane; the cells have wavy margins by which the contiguous cells are dovetailed into one another. The *middle* coat is composed of smooth muscular, and fine elastic, fibres, disposed in a transverse direction. The *external* coat consists of connective tissue, intermixed with smooth muscular fibres longitudinally or obliquely disposed; it forms a protective covering to the other coats, and serves to connect the vessel with the neighbouring structures. In the smaller vessels there are no muscular or elastic fibres, and the wall consists only of a connective tissue coat lined by endothelium (fig. 683). The thoracic duct has a more complex structure than the other lymphatic vessels; it presents a distinct subendothelial layer, similar to that found in the arteries; in the middle coat there is, in addition to the muscular and elastic fibres, a layer of connective tissue with its fibres arranged longitudinally. The larger lymphatic vessels are supplied by nutrient vessels, which are distributed to their outer and middle coats; and here also have been traced many non-medullated nerves in the form of a fine plexus of fibrils.

FIG. 683.—Small lymphatic vessel, from diaphragm of a rabbit. Silvered. $\times 65$.

(fig. 683). The thoracic duct has a more complex structure than the other lymphatic vessels; it presents a distinct subendothelial layer, similar to that found in the arteries; in the middle coat there is, in addition to the muscular and elastic fibres, a layer of connective tissue with its fibres arranged longitudinally. The larger lymphatic vessels are supplied by nutrient vessels, which are distributed to their outer and middle coats; and here also have been traced many non-medullated nerves in the form of a fine plexus of fibrils.

In the lymphatic vessels the valves are placed at much shorter intervals than in the veins. They are most numerous near the lymph-glands, and are found more frequently in the lymphatic vessels of the neck and upper extremity than in those of the lower extremity; they are wanting in the vessels composing the plexiform network in which the lymphatic vessels usually originate on the surface of the body. The valves are formed of thin layers of fibrous tissue covered on both surfaces by endothelium which presents the same arrangement as on the valves of veins (p. 550). They are semilunar in form, and are attached by their convex edges to the wall of the vessel, the concave edges being free and directed along the course of the lymph-current. Usually two valves, of equal size, are found opposite one another; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels; thus, one valve may be of small size and the other increased in proportion. The wall of a lymphatic vessel immediately above the attachment of each segment

of a valve is expanded into a pouch or sinus which gives the vessel, when distended, the knotted or beaded appearance already referred to.

The **lymph-glands** are small oval or bean shaped bodies, situated in the course of lymphatic and lacteal vessels so that the lymph and chyle pass through them on their way to the blood. Each generally presents on one side a slight depression, the *hilum*, through which the blood-vessels enter and leave the gland. The efferent lymphatic vessel also emerges from the gland at this spot, while the afferent vessels enter it at different parts of the periphery. On section (fig. 684), a lymph-gland displays two different structures: an external, of lighter colour--the *cortical*; and an internal, darker--the *medullary*. The cortical structure does not form a complete investment, but is deficient at the hilum, where the medullary portion reaches the surface of the gland; so that the efferent lymphatic vessel is derived directly from the medullary structure, while the afferent vessels empty themselves into the cortical substance.

Structure of lymph-glands (figs. 684, 685).—A lymph-gland consists of (1) a fibrous envelope, or *capsule*, from which a framework of processes (*trabeculae*) proceeds inwards, imperfectly dividing the gland into open spaces freely communicating with each other; (2) a quantity of lymphoid tissue occupying these spaces without

FIG. 684.—Section of a lymph-gland of a cat. Stained with hæmatoxylin and cosin. $\times 15$.

completely filling them; (3) a free supply of blood-vessels, which are supported in the trabeculae; and (4) the *afferent* and *efferent lymphatic vessels* communicating through the lymph-paths in the substance of the gland. The nerves passing into the hilum are few in number and are chiefly distributed to the blood-vessels supplying the gland.

In man the *capsule* and *trabeculae* are composed of connective tissue with some plain muscle-fibres, but in many of the lower animals they consist almost entirely of involuntary muscle. The trabeculae pass inwards towards the centre of the gland for a certain distance—that is to say, for about one-third or one-fourth of the space between the circumference and the centre of the gland. In some animals they are sufficiently well marked to divide the peripheral or cortical portion of the gland into a number of compartments (so-called follicles), but in man this arrangement is not obvious. The larger trabeculae springing from the capsule break up into finer bands, and these interlace to form a meshwork in the central or medullary portion of the gland. The gland-pulp or lymphoid tissue is contained in the spaces formed by the interlacing trabeculae; it does not, however, completely fill the spaces, but leaves, between its outer margin and the enclosing trabeculae, a channel or space, termed the *lymph-path* or *lymph-sinus*; the lymph-path is bridged by a network of retiform tissue (fig. 685).

On account of the peculiar arrangement of the framework, the gland-pulp in the cortical portion is disposed in the form of nodules, and in the medullary part in the form of rounded cords. It consists of ordinary lymphoid tissue (fig. 685), being made up of a delicate network of retiform tissue packed with lymphocytes. The network of the gland-pulp is continuous with that in the lymph-paths, but marked off from it by a closer reticulation; moreover, the fibres of the retiform

tissue of the lymph-paths are continuous with those of the trabeculae. The gland-pulp is traversed by a dense plexus of capillary blood-vessels. The nodules or follicles in the cortical portion of the gland frequently show areas where karyokinetic figures indicate a division of the lymph-corpuscles. These areas are termed *germ-centres*. The actively dividing cells have more abundant protoplasm than those which are not undergoing division, and consequently in stained sections the germ-centres appear clearer than the surrounding gland-pulp.

The *afferent vessels*, as stated above, enter at different parts of the periphery of the gland, and after branching and forming a dense plexus in the substance of the capsule, open into the lymph-sinuses of the cortical part. In doing this they lose all their coats except their endothelial lining, which is continuous with a layer of similar cells lining the lymph-paths. The *efferent vessel* commences from the lymph-sinuses of the medullary portion. The stream of lymph carried to the gland

FIG. 685.--Retiform and adenoid tissue, from a lymph-gland. $\times 255$.

by the afferent vessels thus passes through the plexus in the capsule to the lymph-paths of the cortical portion, where it is exposed to the action of the gland-pulp; flowing through these it enters the paths or sinuses of the medullary portion, and finally emerges from the hilum by means of the efferent vessel. The stream of lymph in its passage through the lymph-sinuses is much retarded by the presence of the reticulum, hence morphological elements, either normal or morbid, are easily arrested and deposited in the sinuses. Many lymph-corpuscles pass with the efferent lymph-stream to join the general blood-stream. The arteries of the gland enter at the hilum, and go to the gland-pulp, to break up into a capillary plexus, either directly or after running in the trabeculae for a certain distance. The veins emerge from the gland at the hilum.

The lymphatic vessels are arranged into a superficial and a deep set. On the surface of the body the *superficial* lymphatic vessels are placed immediately beneath the skin and accompany the superficial veins; they join the deep lymphatic vessels in certain situations. In the interior of the body they lie in the submucous areolar tissue throughout the whole length of the digestive, respiratory and genito-urinary tracts; and in the subserous tissue of the thoracic and abdominal walls. Networks of minute lymphatic vessels are found interspersed among the elements and blood-vessels of the several tissues; the vessels composing the network as well as the meshes between them, are

much larger than those of the capillary plexus. From these networks small vessels emerge, which pass, either to a neighbouring gland, or to join some larger lymphatic trunk. The deep lymphatic vessels, fewer in number, but larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels.

The lymphatic vessels of any part or organ exceed the veins in number, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect.

Applied Anatomy.—The lymphatic vessels and lymph-glands draining any infected area of the body are very liable to become inflamed, resulting in acute or chronic lymphangitis and lymphadenitis. In acute cases the paths of the superficial lymphatic vessels are often marked out on the skin by pain, redness, heat, and swelling, while the lymph-glands swell and may suppurate. Chronic inflammation leads to growth and fibrosis of the lymphatic vessels and the connective tissue round them; obstruction to the passage of the lymph results, as the fibrous tissue contracts and causes stenosis or obliteration of the lymphatic channels, and hard oedema of the involved skin and subcutaneous tissues follows (pachydermia lymphangiectatica). Chronic lymphangitis, together with the blocking of numerous lymphatic vessels by the escaped ova of the minute parasitic worm *Microfilaria nocturna*, is the cause of elephantiasis, a condition common in the tropics and subtropics, and characterised by enormous enlargement and thickening of the skin of some part of the body, most frequently of the leg. Tuberculous and syphilitic enlargements of the lymphatic vessels and lymph-glands are both very commonly met with. Primary tumours of the lymphatic vessels are lymphangioma and endothelioma; the so-called 'congenital cystic hygroma' of the neck, arm, trunk, or thigh, is a cystic lymphangioma. Primary tumours of the lymph-glands may be innocent (lymphadenoma, myxoma, chondroma) or malignant (lymphosarcoma); cancer is never met with as a primary affection, but is extremely common secondarily to cancer of some other part of the body.

The appearance of secondary malignant deposits or of secondary infection in parts of the body that seem not to be directly associated by any lymphatic connexion with the seat of the primary growth or infection has often been observed, and explained as due to 'retrograde transport' of cancer-cells or bacteria by a reversed flow of lymph. Welninsky,* however, believes that the explanation is to be found in the fact that when the infected lymph-glands have grown to a certain size they no longer permit the normal flow of lymph through them, and that under these circumstances very delicate lymphatic connexions, whose existence normally remains unsuspected, develop to a surprising extent between groups of lymph-glands that at first sight appear to be unconnected with one another.

THORACIC DUCT

The thoracic duct (fig. 683) conveys the chyle and the greater part of the lymph into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those of the right side of the head, neck, and thoracic wall, the right upper extremity, right lung, right side of the heart, and part of the convex surface of the liver. In the adult it varies in length from 38 cm. to 45 cm., and extends from the second lumbar vertebra to the root of the neck. It begins in a triangular dilatation, the *cisterna chyli*, which is situated on the front of the bodies of the first and second lumbar vertebrae, to the right side of and behind the aorta, by the side of the right crus of the Diaphragm. It enters the thorax through the aortic hiatus of the Diaphragm, and ascends through the posterior mediastinal cavity with the aorta on its left and the azygos vein on its right side. Behind it in this region are the vertebral column, the right intercostal arteries, and the hemiazygos and accessory hemiazygos veins. In front of it are the Diaphragm, œsophagus, and pericardium, the last being separated from it by a recess of the right pleural cavity. Opposite the fifth thoracic vertebra, it inclines towards the left side, enters the superior mediastinal cavity, and ascends behind the aortic arch and the thoracic part of the left subclavian artery and between the left side of the œsophagus and the left pleura, to the upper orifice of the thorax. Passing into the neck it forms an arch which rises about 3 cm. or 4 cm. above the clavicle and turns forwards anterior to the first part of the subclavian artery, the vertebral artery and vein, and the thyrocervical trunk or its branches. It also passes in front of the phrenic nerve and the medial border of the Scalenus anterior, but is

* *Berliner Klin. Woch.*, 1905, No. 24, p. 743.

separated from these two structures by the prevertebral fascia. In front of it are the left common carotid artery, vagus nerve, and internal jugular vein; it ends by opening into the angle of junction of the left subclavian vein with the left internal jugular vein. The thoracic duct, at its commencement, is about equal in diameter to a goose-quill, but it diminishes considerably in calibre in the middle of the thorax, and is again slightly dilated just before its termination. It is generally flexuous, and constricted at intervals so as to present a varicose appearance. Not infrequently it divides in the middle of its course into two vessels of unequal size which soon reunite, or into several branches which form a plexiform interlacement. It occasionally divides at its upper part into two branches, right and left: the left ending in the usual manner, while the right opens into the right subclavian vein, in connexion with the right lymphatic duct.

The thoracic duct has several valves; at its termination it is provided with a pair, the free borders of which are turned towards the vein, so as to prevent the passage of venous blood into the duct.

The cisterna chyli (fig. 687) receives the two lumbar lymphatic trunks, right and left, and the intestinal lymphatic trunk. The *lumbar trunks* are formed by the union of the efferent vessels from the lateral aortic lymph-glands; they receive the lymph from the lower limbs, from the walls and viscera of the pelvis, from the kidneys and suprarenal glands, and the deep lymphatics of the greater part of the abdominal wall. The *intestinal trunk* receives the lymph from the stomach, intestine, pancreas and spleen, and from the lower and front part of the liver.

Tributaries.—Opening into the commencement of the thoracic duct, on either side, is a descending trunk from the posterior intercostal lymph-glands of the lower six or seven intercostal spaces. In the thorax the duct is joined on either side by a trunk which drains the upper lumbar lymph-glands and pierces the crus of the Diaphragm. It also receives the offerents from the posterior mediastinal lymph-glands and from the posterior intercostal lymph-glands of the upper six left spaces. In the neck it is joined by the *left jugular*

FIG. 686.—The thoracic and right lymphatic ducts.

trunk from the left side of the head and neck, and *left subclavian trunk* from the left superior extremity; sometimes it is joined by the *left bronchomediastinal trunk*, but this trunk usually opens independently into the junction of the left subclavian and internal jugular veins.

The **right lymphatic duct** (fig. 686), about 1.25 cm. in length, courses along the medial border of the *Scalenus anterior* at the root of the neck, and

FIG. 687.—Modes of origin of thoracic duct. (Poirier and Charpy.)

ends by opening into the angle of junction of the right subclavian and right internal jugular veins. Its orifice is guarded by two semilunar valves which prevent the passage of venous blood into the duct.

Tributaries.—The right lymphatic duct receives the lymph from the right side of the head and neck through the *right jugular trunk*; from the right upper extremity through the *right subclavian trunk*; from the right side of the thorax, right lung, right side of the heart, and part of the convex surface of the liver, through the *right bronchomediastinal trunk*. These three trunks frequently open separately in the angle of union of the two veins (fig. 688).

a. Jugular trunk. b. Subclavian trunk. c. Bronchomediastinal trunk. d. Right lymphatic trunk. e. Lymph-gland of internal mammary chain. f. Lymph-gland of deep cervical chain.

Applied Anatomy.—Blockage of the thoracic duct by mature specimens of the minute parasitic worm *Microfilaria nocturna* gives rise to stasis of the chyle, and to its passage in various abnormal directions on its course past the obstruction. The neighbouring abdominal, renal, and pelvic lymphatics become enlarged, varicose, and tortuous, and

chyle may make its way into the urino (chyluria), the tunica vaginalis (chylocele), the abdominal cavity (chylous ascites), or the pleural cavity (chylous pleural effusion), in consequence of rupture of some of these distended lymphatic vessels.

Gunshot wounds of the chest involving laceration of the thoracic duct and the escape of chyle into the pleural cavity have been described. It appears that if left alone, such lacerations tend to heal and close up spontaneously.

The thoracic duct may be secondarily infected in intestinal or pulmonary tuberculosis, and may contain either miliary tubercles, caseating tuberculous masses, or even tuberculous ulcers. It is often the seat of secondary carcinomatous deposits in cases of cancer of some abdominal viscus, becoming infiltrated throughout until it becomes a stiff moniliform rod as thick as a pencil, with multiple stenoses and dilatations of its lumen; in such cases the left supraclavicular lymph-glands are often infected and enlarged, while the lungs remain free from secondary growths.

LYMPH GLANDS OF THE HEAD AND NECK

1. The lymph-glands of the head (fig. 689) consist of the following groups :

Occipital.

Posterior auricular.

Anterior auricular.

Parotid.

Facial.

Deep facial.

Lingual.

FIG. 689.—Superficial lymph-glands and lymphatic vessels of head and neck.

The occipital lymph-glands, one to three in number, are placed on the back of the head close to the margin of the Trapezius and resting on the insertion of the Semispinalis capitis. Their afferent vessels drain the lymph from the

occipital region of the scalp; their efferents convey it to the superior deep cervical lymph-glands.

The **posterior auricular lymph-glands**, usually two in number, are situated on the mastoid insertion of the Sternocleidomastoideus, beneath the Auricularis posterior. Their afferent vessels drain the posterior part of the temporoparietal region, the upper part of the cranial surface of the auricula or pinna, and the back of the external acoustic meatus; their efferents pass to the superior deep cervical lymph-glands.

The **anterior auricular lymph-glands**, from one to three in number, lie immediately in front of the tragus. Their afferents drain the lateral surface of the auricula and the skin of the adjacent part of the temporal region; their efferents pass to the superior deep cervical lymph-glands.

The **parotid lymph-glands** form two groups, one imbedded in the substance of the parotid salivary gland, and the other, or subparotid group, placed on the lateral wall of the pharynx. Occasionally small lymph-glands are found in the subcutaneous tissue over the parotid salivary gland. The afferents of the subparotid lymph-glands drain the nasal part of the pharynx and the posterior parts of the nasal cavities; their efferents pass to the superior deep cervical lymph-glands. The afferents of the remaining parotid lymph-glands drain the root of the nose, the eyelids, the frontotemporal region, the external acoustic meatus and the tympanic cavity, possibly also the posterior parts of the palate and of the floor of the nasal cavity. Their efferents pass to the superior deep cervical lymph-glands.

The **facial lymph-glands** comprise three groups: (a) *infraorbital*, scattered over the infraorbital region from the groove between the nose and cheek to the zygomatic arch; (b) *buccinator*, one or more on the Buccinator opposite the angle of the mouth; (c) *supramandibular*, on the outer surface of the mandible in front of the Masseter and in contact with the external maxillary artery and anterior facial vein. Their afferents drain the eyelids, the conjunctiva, and the skin and mucous membrane of the nose and cheek; their efferents pass to the anterior auricular and submaxillary lymph-glands.

The **deep facial lymph-glands** are placed beneath the ramus of the mandible, on the outer surface of the Pterygoideus externus, in relation to the internal maxillary artery. Their afferents drain the temporal and infratemporal fossæ, the palate and the nasal part of the pharynx; their efferents pass to the superior deep cervical lymph-glands.

The **lingual lymph-glands** are two or three small nodules lying on the Hyoglossus, and between the Genioglossi. They are merely glandular nodules in the course of the lymphatic vessels of the tongue.

2. The **lymph-glands of the neck** include the following groups:

Retropharyngeal.
Submaxillary.
Submental.

Anterior cervical.
Superficial cervical.
Deep cervical.

The **retropharyngeal lymph-glands** (fig. 691), from one to three in number, lie in the buccopharyngeal fascia, behind the upper part of the pharynx and in front of the arch of the atlas, being separated, however, from the latter by the Longus capitis. Their afferents drain the nasal cavities, the nasal part of the pharynx, and the auditory tubes; their efferents pass to the superior deep cervical lymph-glands.

The **submaxillary lymph-glands** (fig. 690), three to six in number, are placed beneath the body of the mandible in the submaxillary triangle, and rest on the superficial surface of the submaxillary salivary gland. One (the *middle lymph-gland of Stahr*) lies on the external maxillary artery as this artery turns over the mandible, and is the most constant of the series; small lymph-glands are sometimes found imbedded in the submaxillary salivary gland or lying on its deep surface. The afferents of the submaxillary lymph-glands drain the medial palpebral commissure, the cheek, the side of the nose, the upper lip, the lateral part of the lower lip, the gums, and the anterior part of the margin of the tongue; efferent vessels from the facial and submental lymph-glands also enter the submaxillary lymph-glands. Their efferent vessels pass to the superior deep cervical lymph-glands.

The **submental or suprahyoid lymph-glands** are placed between the

anterior bellies of the two Digastric muscles. Their afferents drain the central portions of the lower lip and floor of the mouth and the apex of the tongue; their efferents pass partly to the submaxillary lymph-glands and partly to a lymph-gland of the deep cervical group situated on the internal jugular vein at the level of the cricoid cartilage.

The **anterior cervical lymph-glands** are placed in front of the larynx and trachea, and consist of a *superficial* and a *deep* set. The lymph-glands of the superficial set lie alongside the anterior jugular vein, but are inconstant in number and size. The lymph-glands of the deep set comprise: (a) the *infrahyoid lymph-glands* which lie in front of the hyothyroid membrane, and receive their afferents from the neighbourhood of the epiglottis; (b) the *prelaryngeal lymph-glands* which lie on the middle cricothyroid ligament; and (c) the *pretracheal lymph-glands* which are placed in front of the trachea, alongside the inferior thyroid veins. The prelaryngeal and pretracheal groups receive their afferents from the larynx, the thyroid gland, and the cervical part of the trachea; their efferents pass to the deep cervical lymph-glands.

FIG. 690.—Lymphatics of the face. (After Küttner.)

The **superficial cervical lymph-glands** (fig. 689) lie in close relationship with the external jugular vein as it emerges from the parotid gland, and are superficial to the Sternocleidomastoideus. Their afferents drain the parotid region and the lower part of the auricula, while their efferents pass round the anterior margin of the Sternocleidomastoideus to join the superior deep cervical lymph-glands.

The **deep cervical lymph-glands** (figs. 691, 692) are numerous and of large size; they form a chain along the carotid sheath, lying by the side of the pharynx, œsophagus, and trachea, and extending from the base of the skull to the root of the neck. They are usually described in two groups: (1) the *superior deep cervical lymph-glands* lying under the Sternocleidomastoideus in close relation with the accessory and hypoglossal nerves, and the internal jugular vein, some of the glands lying in front of and others behind the vein; (2) the *inferior deep cervical lymph-glands* extending beyond the posterior margin of the Sternocleidomastoideus into the supraclavicular triangle, where they are closely related to the brachial plexus and subclavian vein. A few minute *paratracheal lymph-glands* are situated alongside the recurrent nerves on the lateral aspects of the trachea and œsophagus. The superior deep cervical lymph-glands drain the occipital portion of the scalp, the auricula,

the back of the neck, a considerable part of the tongue, the larynx, thyroid gland, trachea, nasal part of the pharynx, nasal cavities, palate, and œsophagus. They receive also the efferent vessels from all the other lymph-glands of the head and neck, except those from the inferior deep cervical lymph-glands. The inferior deep cervical lymph-glands drain the back of the scalp and neck, the superficial pectoral region, and part of the arm (p. 721). In addition, they receive vessels from the superior deep cervical lymph-glands. The efferents of the superior deep cervical lymph-glands pass partly to the inferior deep cervical lymph-glands and partly to a trunk which unites with the efferent vessel of the inferior deep cervical lymph-glands and forms the *jugular trunk*. On the right side, this trunk ends in the junction of the internal jugular and subclavian veins; on the left side it joins the thoracic duct.

LYMPHATIC VESSELS OF THE HEAD AND NECK

The *lymphatic vessels of the scalp* are divisible into (a) those of the frontal region, which drain into the anterior auricular and parotid lymph-glands; (b) those of the temporoparietal region, which end in the parotid and posterior auricular lymph-glands; and (c) those of the occipital region, which terminate partly in the occipital lymph-glands and partly in a trunk which runs down along the posterior border of the Sternocleidomastoideus to end in the inferior deep cervical lymph-glands.

FIG. 691.—Lymphatics of the pharynx. (Poirier and Charpy.)

The *lymphatic vessels of the auricula and external acoustic meatus* are also divisible into three groups: (a) an anterior, from the lateral surface of the auricula and anterior wall of the meatus to the anterior auricular lymph-glands; (b) a posterior, from the margin of the auricula, the upper part of its cranial surface, the internal surface and posterior wall of the meatus to the posterior auricular and superior deep cervical lymph-glands; (c) an inferior, from the floor of the meatus and from the lobule of the auricula to the superficial and superior deep cervical lymph-glands.

The *lymphatic vessels of the face* (figs. 689, 690) are more numerous than those of the scalp. Those from the eyelids and conjunctiva terminate partly in the submaxillary, but mainly in the parotid, lymph-glands. The vessels from the posterior part of the cheek also pass to the parotid lymph-glands, while those from the anterior portion of the cheek, the side of the nose, the upper lip, and the lateral portions of the lower lip end in the submaxillary lymph-glands. The deeper vessels from the temporal and infratemporal fossæ pass

to the deep facial and superior deep cervical lymph-glands. The deeper vessels of the cheek and lips end, like the superficial, in the submaxillary lymph-glands. Both superficial and deep vessels of the central part of the lower lip run to the submental lymph-glands.

The *lymphatic vessels of the nasal cavities* can be injected from the subdural and subarachnoid cavities. Those from the anterior parts of the nasal cavities communicate with the lymphatic vessels of the skin of the nose, and end in the submaxillary lymph-glands; those from the posterior two-thirds of the nasal cavities and from the accessory air-sinuses of the nose pass partly to the retropharyngeal and partly to the superior deep cervical lymph-glands.

FIG. 692.—Lymphatics of the tongue. (Poirier.)

Lymphatic vessels of the mouth.—The vessels of the gums pass to the submaxillary lymph-glands; those of the hard palate are continuous in front with those of the upper gum, but run backwards to pierce the Constrictor pharyngis superior, and end in the superior deep cervical and subparotid lymph-glands; those of the soft palate pass backwards and lateralwards and end partly in the retropharyngeal and subparotid, and partly in the superior deep cervical lymph-glands. The vessels of the anterior part of the floor of the mouth go either directly to the inferior lymph-glands of the superior deep cervical group, or indirectly, through the submental lymph-glands; the vessels from the rest of the floor of the mouth pass to the submaxillary and superior deep cervical lymph-glands.

The *lymphatic vessels of the palatine tonsil*, usually three to five in number, pierce the buccopharyngeal fascia and Constrictor pharyngis superior and pass

between the Stylohyoideus and the internal jugular vein to the superior deep cervical lymph-glands. Most of them end in a lymph-gland which lies at the side of the posterior belly of the Digastricus, on the internal jugular vein; occasionally one or two additional vessels run to small lymph-glands on the lateral side of the vein, under cover of the Sternocleidomastoideus.

The *lymphatic vessels of the tongue* (fig. 692) are drained chiefly into the deep cervical lymph-glands lying between the posterior belly of the Digastricus and the superior belly of the Omohyoideus; one gland situated at the bifurcation of the common carotid artery is so intimately associated with these lymphatic vessels that it is known as the *principal lymph-gland of the tongue*. The lymphatic vessels of the tongue may be divided into four groups: (1) apical, from the apex of the tongue to the suprahyoid lymph-glands and principal lymph-gland of the tongue; (2) lateral, from the margin of the tongue, some of which pierce the Mylohyoideus to end in the submaxillary lymph-glands, others pass down on the Hyoglossus to the superior deep cervical lymph-glands; (3) basal, from the region of the papillæ vallatæ to the superior deep cervical lymph-glands; and (4) median, a few of which perforate the Mylohyoideus to reach the submaxillary lymph-glands, while the majority turn round the posterior border of the muscle to enter the superior deep cervical lymph-glands; some of the median vessels drain into the submaxillary lymph-glands of the opposite side.

The *lymphatic vessels of the skin and muscles of the neck* pass to the deep cervical lymph-glands. From the upper part of the *pharynx* the lymphatic vessels pass to the retropharyngeal lymph-glands; from the lower part to the deep cervical lymph-glands. From the *larynx* two sets of vessels arise, an upper and a lower. The vessels of the upper set pierce the hyothyroid membrane and join the superior deep cervical lymph-glands. Of the lower set, some pierce the conus elasticus and join the pretracheal and prelaryngeal lymph-glands; others run between the cricoid cartilage and first tracheal ring and enter the inferior deep cervical lymph-glands. The lymphatic vessels of the *thyroid gland* consist of an upper set, which accompanies the superior thyreoid artery and enters the superior deep cervical lymph-glands, and a lower, which runs partly to the pretracheal lymph-glands and partly to the small paratracheal lymph-glands which accompany the recurrent nerves. The paratracheal lymph-glands also receive lymphatic vessels from the cervical portion of the trachea.

Applied Anatomy.—The superficial and deep cervical lymph-glands often become infected from inflammatory conditions about the mouth, teeth, tonsil and pharynx. When suppuration occurs in the deep group it is apt to spread widely beneath the deep cervical fascia unless relieved by early incision.

The cervical lymph-glands are very frequently the seat of tuberculous disease. This condition may be set up by some lesion in those parts from which they receive their lymph. It is very desirable for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of lymph-glands to important structures, as in order to eradicate them by operation a long and difficult dissection may be required.

The same can also be said of these lymph-glands when they become infiltrated with carcinomatous growth secondary to disease of the lip, tongue, palate, or pharynx. At times it will be found necessary to remove a portion of the internal jugular vein, previously ligatured, with the mass of glands.

LYMPH-GLANDS OF THE UPPER EXTREMITY

7X The lymph-glands of the upper extremity are divided into two sets, *superficial* and *deep*.

The *superficial lymph-glands* (fig. 693) are few and of small size. One or two *supratrochlear* lymph-glands are placed above the medial epicondyle of the humerus, on the medial side of the basilic vein. Their afferents drain the middle, ring, and little fingers, the medial portion of the hand, and the superficial area over the ulnar side of the forearm; these vessels are, however, in free communication with the other lymphatic vessels of the forearm. Their efferents accompany the basilic vein and join the deeper vessels. One or two

deltoideopectoral lymph-glands are found beside the cephalic vein, between the Pectoralis major and Deltoideus, immediately below the clavicle. They are situated in the course of a collecting trunk which drains the lateral side of the arm and forearm.

The **deep lymph-glands** are chiefly grouped in the axilla, although a few may be found in the forearm, in the course of the radial, ulnar, and interosseous vessels, and in the arm along the medial side of the brachial artery.

FIG. 698.—The superficial lymph-glands and lymphatic vessels of the upper extremity.

The **axillary lymph-glands** (fig. 694) are of large size; they vary from twenty to thirty in number, and may be arranged in the following groups:

1. A lateral group of from four to six lymph-glands lies in relation to the medial and posterior aspects of the axillary vein; the afferents of this group drain the whole arm with the exception of that portion whose lymphatic vessels accompany the cephalic vein. The efferent vessels pass partly to the central and subclavicular groups of axillary lymph-glands, and partly to the inferior deep cervical lymph-glands.

2. An anterior or pectoral group, consisting of four or five lymph-glands, lies along the lower border of the Pectoralis minor, in relation with the lateral thoracic artery. Its afferents drain the skin and muscles of the anterior and

lateral thoracic walls, and the central and lateral parts of the mamma; its efferents pass partly to the central, and partly to the subclavicular groups of axillary lymph-glands.

3. A posterior or subscapular group of six or seven lymph-glands is placed along the lower margin of the posterior wall of the axilla in the course of the subscapular artery. The afferents of this group drain the skin and muscles of the lower part of the back of the neck and of the posterior thoracic wall; their efferents pass to the central group of axillary lymph-glands.

FIG. 694.—Lymphatics of the mamma, and the axillary lymph-glands (semi-diagrammatic). (Poirier and Charpy.)

4. A central or intermediate group of three or four large lymph-glands is imbedded in the adipose tissue near the base of the axilla. Its efferents are the efferent vessels of all the preceding groups of axillary lymph-glands: its efferents pass to the subclavicular group of lymph-glands.

5. A medial or subclavicular group of six to twelve lymph-glands is situated partly posterior to the upper portion of the Pectoralis minor and partly above the upper border of this muscle. The only direct territorial afferents of this group are those which accompany the cephalic vein and one which drains the upper peripheral part of the mamma, but it receives the efferents of all the other axillary lymph-glands. The efferent vessels of this group unite to form the subclavian trunk, which opens either directly into the junction of the internal jugular and subclavian veins or into the jugular lymphatic trunk: on the left side it may end in the thoracic duct. A few efferents from the subclavicular group usually pass to the inferior deep cervical lymph-glands.

Applied Anatomy.—Enlargement of the axillary lymph-glands is very often found in malignant disease and also in infective processes implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the front and side of the abdomen, or the hand, forearm, and arm.

LYMPHATIC VESSELS OF THE UPPER EXTREMITY

The *lymphatic vessels of the upper extremity* consist of two sets, superficial and deep.

The *superficial lymphatic vessels* (fig. 695) commence in the lymphatic plexus which everywhere pervades the skin; the meshes of the plexus are much finer in the palm and on the flexor aspects of the digits than elsewhere. The digital plexuses are drained by a pair of vessels which run on the sides of each digit, and incline backwards to reach the dorsum of the hand. From the dense plexus of the palm, vessels pass in different directions, viz. upwards towards the wrist, downwards to join the digital vessels, medialwards to join the vessels on the ulnar border of the hand, and lateralwards to those on the thumb. Several vessels from the central part of the plexus unite to form a trunk, which passes round the metacarpal bone of the index finger to join the vessels on the back of that digit and on the back of the thumb. As the lymphatic vessels run upwards in front of and behind the wrist, they are collected into groups, which accompany the cephalic, median antibrachial, and basilic veins in the forearm. A few of those on the ulnar side end in the supratrochlear lymph-glands, but the majority pass directly to the lateral group of axillary lymph-glands. Some of the vessels on the radial side are collected into a trunk which ascends with the cephalic vein to the deltoideopectoral lymph-glands; the efferents from this group pass either to the sub-clavicular axillary lymph-glands or to the inferior deep cervical lymph-glands.

The *deep lymphatic vessels* accompany the deep blood-vessels. In the forearm, they consist of four sets, corresponding with the radial, ulnar, volar interosseous, and dorsal interosseous arteries; they communicate at intervals with the superficial lymphatic vessels, and some of them end in the lymph-glands which are occasionally found beside the arteries. In their course upwards, a few end in the supratrochlear lymph-glands, but most of them pass to the lateral group of axillary lymph-glands. •

FIG. 695.—Lymphatic vessels of the dorsal surface of the hand. (Sappey.)

R

LYMPH-GLANDS OF THE LOWER EXTREMITY

The *lymph-glands of the lower extremity* consist of three sets:—the anterior tibial, the popliteal and the inguinal.

The *anterior tibial lymph-gland* is small and inconstant; it lies on the interosseous membrane in relation to the upper part of the anterior tibial vessels.

The *popliteal lymph-glands* (fig. 696), small in size and six or seven in number, are imbedded in the fat contained in the popliteal fossa. One lies

immediately beneath the popliteal fascia, near the terminal part of the small saphenous vein, and drains the region from which this vein derives its tributaries. Another is placed between the popliteal artery and the posterior surface of the knee-joint; it receives the lymphatic vessels from the knee-joint together with those which accompany the genicular arteries. The other lymph-glands lie at the sides of the popliteal vessels, and receive as afferents the trunks which accompany the anterior and posterior tibial vessels. The efferents of the popliteal lymph-glands pass almost entirely alongside the femoral vessels to the deep subinguinal lymph-glands, but a few may accompany the great saphenous vein, and end in the superficial subinguinal lymph-glands.

FIG. 696.—Lymph-glands of popliteal fossa. (Poirier and Charpy.)

The inguinal lymph-glands (fig. 697), from twelve to twenty in number, are situated at the upper part of the femoral triangle. They may be divided into two groups by a horizontal line at the level of the termination of the great saphenous vein; those lying above this line are termed the superficial inguinal lymph-glands, and those below it the subinguinal lymph-glands, the latter group consisting of a superficial and a deep set.

The *superficial inguinal lymph-glands* form a chain immediately below the inguinal ligament. They receive as afferents the lymphatic vessels from the skin of the penis, scrotum, perinæum, buttock, and abdominal wall below the level of the umbilicus; they also receive lymphatic vessels from the anal canal and from the mucous membrane of the anterior part of the urethra.

The *superficial subinguinal lymph-glands* are placed on either side of the upper part of the great saphenous vein; their afferents consist chiefly of the superficial lymphatic vessels of the lower extremity, except the back and lateral side of the calf of the leg, but they also receive some of the vessels which drain the skin of the penis, scrotum, perinæum, and buttock.

The *deep subinguinal lymph-glands* vary from one to three in number, and are placed under the fascia lata, on the medial side of the femoral vein. When three are present, the lowest is situated just below the junction of the great saphenous and femoral veins, the middle in the femoral canal, and the highest in the lateral part of the femoral ring. The middle one is the most inconstant,

but the highest, the *lymph-gland of Cloquet or Rosenmüller*, is also frequently absent. They receive as afferents the deep lymphatic vessels which accompany the femoral vessels, the lymphatic vessels from the glans penis (vel clitoridis), and also some of the efferents from the superficial subinguinal lymph-glands; their efferents pass through the femoral canal to the external iliac lymph-glands.

Applied Anatomy.—Inflammation and suppuration of the popliteal lymph-glands are most commonly due to a sore on the lateral side of the heel.

The inguinal and subinguinal lymph-glands frequently become enlarged in diseases implicating the parts from which their lymphatic vessels originate. Thus in malignant or syphilitic affections of the prepuce and penis, or labia majora, in cancer of the scrotum, in abscess in the perineum, or in similar diseases affecting the skin and superficial structures in those parts, or the sub-umbilical part of the abdominal wall, or the gluteal region, the upper group of lymph-glands is almost invariably enlarged, the lower groups being implicated in diseases affecting the lower limb.

FIG. 697.—The superficial lymph-glands and lymphatic vessels of the lower extremity.

LYMPHATIC VESSELS OF THE LOWER EXTREMITY

The *lymphatic vessels of the lower extremity* consist of two sets, superficial and deep, and in their distribution correspond closely with the veins.

The *superficial lymphatic vessels* lie in the superficial fascia, and are divisible into two groups: a medial, which follows the course of the great saphenous vein; and a lateral, which accompanies the small saphenous vein. The vessels of the *medial group* (fig. 697) are larger and more numerous than those of the lateral group, and commence on the tibial side and dorsum of the foot; they ascend in front of and behind the medial malleolus, run up the leg with the great saphenous vein, pass with it behind the medial condyle of the femur, and accompany it to the groin, where they end in the subinguinal group of superficial lymph-glands. The vessels of the *lateral group* arise from the fibular side of the foot; some ascend in front of the leg, and cross the tibia below the knee to join the lymphatics on the medial side of the thigh; others pass behind the lateral malleolus, and, accompanying the small saphenous vein, enter the popliteal lymph-glands.

The *deep lymphatic vessels* are few in number, and accompany the deep blood-vessels. In the leg, they consist of three sets, anterior tibial, posterior tibial, and peroneal, which accompany the corresponding blood-vessels, two or three with each artery; they enter the popliteal lymph-glands.

The deep lymphatic vessels of the gluteal and ischial regions follow the course of the corresponding blood-vessels. Those accompanying the superior gluteal vessels end in a lymph-gland which lies on the intrapelvic portion of the superior gluteal artery, near the upper border of the greater sciatic foramen. Those following the inferior gluteal vessels traverse one or two small lymph-glands which lie below the Piriformis muscle, and end in the hypogastric lymph-glands.

LYMPH-GLANDS OF THE ABDOMEN AND PELVIS

The lymph-glands of the abdomen and pelvis may be divided, from their situations, into: 1. *parietal*, lying behind the peritoneum and in close association with the larger blood-vessels; and 2. *visceral*, which are found in relation to the visceral arteries.

FIG. 698.—The parietal lymph-glands of the pelvis. (Cunéo and Marcille.)

1. The **parietal lymph-glands** (figs. 698, 699) include the following groups:

External iliac.	Iliac circumflex.	Lumbar	Lateral aortic.
Common iliac.	Hypogastric.		Pre-aortic.
Inferior epigastric.	Sacral.		Retro-aortic.

The external iliac lymph-glands, from eight to ten in number, lie along the external iliac vessels. They are arranged in three groups, one on the lateral, another on the medial, and a third on the anterior aspect of the vessels; the third group is, however, sometimes absent. Their principal afferents are derived from the inguinal and subinguinal lymph-glands, the deep lymphatic vessels of the abdominal wall below the umbilicus and of the adductor region of the thigh, and the lymphatic vessels from the glans penis vel clitoridis, the membranous urethra, the prostate, the fundus of the urinary bladder, the cervix uteri, and upper part of the vagina.

FIG. 699.—Iliopelvic lymph-glands (lateral view). (Cunéo and Marcille.)

The common iliac lymph-glands, four to six in number, are grouped behind and on the sides of the common iliac artery, one or two (subaortic) being placed below the bifurcation of the aorta, in front of the fifth lumbar vertebra. They drain chiefly the hypogastric and external iliac lymph-glands, and their efferents pass to the lateral aortic lymph-glands.

The inferior epigastric lymph-glands, three or four in number, are placed alongside the lower portions of the inferior epigastric vessels.

The iliac circumflex lymph-glands, two to four in number, lie along the course of the deep iliac circumflex vessels; they are sometimes absent.

The hypogastric lymph-glands (fig. 699) surround the hypogastric vessels, and receive the lymphatic vessels corresponding to the distribution of the branches of the hypogastric artery, i.e. they receive lymphatic vessels from all the pelvic viscera, from the deeper parts of the perinæum, including the membranous and cavernous portions of the urethra, and from the buttock and back of the thigh. An *obturator lymph-gland* is sometimes present in the upper part of the obturator foramen.

The sacral lymph-glands are placed in the concavity of the sacrum, in relation to the middle and lateral sacral arteries; they receive lymphatic vessels from the rectum and posterior wall of the pelvis.

The efferents of the hypogastric and sacral groups end in the common iliac lymph-glands.

The **lumbar lymph-glands** are very numerous, and consist of right and left lateral aortic, pre-aortic, and retro-aortic groups.

The *right lateral aortic lymph-glands* are situated partly in front of the inferior vena cava, near the termination of the renal vein, and partly behind it on the origin of the Psoas major, and on the right crus of the Diaphragm. The *left lateral aortic lymph-glands* form a chain on the left side of the abdominal aorta in front of the origin of the Psoas major and left crus of the Diaphragm. The lymph-glands on either side receive (a) the efferents of the common iliac lymph-glands; (b) the lymphatics from the testis in the male and from the ovary, uterine tube, and body of the uterus in the female; (c) the lymphatics from the kidney and suprarenal gland; and (d) the lymphatics draining the lateral abdominal muscles and accompanying the lumbar veins. Most of

FIG. 700.—Lymphatics of stomach, &c. (Jamieson and Dobson.)

the efferent vessels of the lateral aortic lymph-glands converge to form the *right and left lumbar trunks* which join the cisterna chyli, but some enter the pre- and retro-aortic lymph-glands, and others pierce the crura of the Diaphragm to join the lower end of the thoracic duct. The *pre-aortic lymph-glands* lie in front of the aorta, and may be divided into *celiac*, *superior mesenteric*, and *inferior mesenteric* groups, arranged around the origins of the corresponding arteries. They receive a few vessels from the lateral aortic lymph-glands, but their principal afferents are derived from the viscera supplied by the three arteries with which they are associated. Some of their efferents pass to the retro-aortic lymph-glands, but the majority unite to form the *intestinal trunk*, which enters the cisterna chyli. The *retro-aortic lymph-glands* are placed below the cisterna chyli, on the bodies of the third and fourth lumbar vertebrae. They receive lymphatic vessels from the lateral and pre-aortic lymph-glands, while their efferents end in the cisterna chyli.

2. The **visceral lymph-glands** are associated with the branches of the celiac, superior and inferior mesenteric arteries. Those related to the branches of the celiac artery form three sets, gastric, hepatic, and pancreaticocolical.

The **gastric lymph-glands** (figs. 700, 701) consist of two sets, superior and inferior.

The **superior gastric lymph-glands** accompany the left gastric artery and are divisible into three groups, viz.: (a) *upper*, on the stem of the artery; (b) *lower*,

accompanying the descending branches of the artery along the cardiac half of the lesser curvature of the stomach, between the two layers of the lesser omentum ; and (c) *paracardial*, disposed in a manner comparable to a chain of beads around the neck of the stomach (Jamieson and Dobson).^{*} They receive their afferents from the stomach, and also some vessels from the pylorus ; their efferents pass to the coeliac group of pre-aortic lymph-glands.

The **inferior gastric lymph-glands**, four to seven in number, lie between the two layers of the greater omentum along the pyloric half of the greater curvature of the stomach. They receive afferents from the stomach ; their efferents mostly pass to the subpyloric lymph-glands.

FIG. 701.—Lymphatics of stomach, &c. The stomach has been turned upwards. (Jamieson and Dobson.)

The **hepatic lymph-glands** (fig. 700) consist of the following groups : (a) *hepatic*, on the stem of the hepatic artery, and extending upwards along the common bile-duct, between the two layers of the lesser omentum, as far as the porta hepatis ; one member of this group, the *cystic lymph-gland*, is placed near the neck of the gall-bladder ; (b) *subpyloric*, four or five in number, in close relation to the bifurcation of the gastroduodenal artery, in the angle between the superior and descending parts of the duodenum ; an outlying member of this group is sometimes found above the duodenum on the right gastric (pyloric) artery. The lymph-glands of the hepatic chain receive afferents from the stomach, duodenum, liver, gall-bladder, and pancreas ; their efferents join the coeliac group of pre-aortic lymph-glands.

The **pancreaticolienal lymph-glands** (fig. 701) accompany the lienal (splenic) artery, and are situated in relation to the posterior surface and upper border of the pancreas ; one or two members of this group are found in the

^{*} *Lancet*, April 20 and 27, 1907.

gastrolenal ligament (Jamieson and Dobson, *loc. cit.*). Their afferents are derived from the stomach, spleen, and pancreas; their efferents join the coeliac group of pre-aortic lymph-glands.

The superior mesenteric lymph-glands may be divided into three principal groups: mesenteric, ileocolic, and mesocolic.

The *mesenteric lymph-glands* lie between the layers of the mesentery. They vary from one hundred to one hundred and fifty in number, and consist of three sets, viz.: one lying close to the wall of the small intestine, amongst the terminal twigs of the superior mesenteric artery; a second, in relation to the loops and primary branches of the jejunal and ileal vessels; and a third along the upper part of the trunk of the superior mesenteric artery.

Applied Anatomy.—Enlargement of the mesenteric lymph-glands is seen in most diseased conditions of the intestinal tract, and is well marked in enteric fever, tuberculous ulceration or malignant growths of the bowel. The enlarged lymph-glands can often be palpated through the wall of the abdomen.

FIG. 702.—The lymphatics of cæcum and vermiform process, from the front. (Jamieson and Dobson.)

The *ileocolic lymph-glands* (figs. 702, 703), from ten to twenty in number, form a chain around the ileocolic artery, but show a tendency to subdivision into two groups, one near the duodenum and another on the lower part of the trunk of the artery. Where the vessel divides into its terminal branches the chain is broken up into several groups, viz.: (a) *ileal*, in relation to the ileal branch of the artery; (b) *anterior ileocolic*, usually of three glands, in the ileocolic fold, near the wall of the cæcum; (c) *posterior ileocolic*, mostly placed in the angle between the ileum and the colon, but partly lying behind the cæcum at its junction with the ascending colon; (d) a single gland in the mesenteriole of the vermiform process; (e) *right colic*, along the medial side of the ascending colon.

The *mesocolic lymph-glands* are numerous, and lie between the layers of the transverse mesocolon, in close relation to the transverse colon; they are best developed in the neighbourhood of the right and left colic flexures. One or two small lymph-glands are occasionally seen along the trunk of the right

colic artery, and others are found in relation to the trunk and branches of the middle colic artery.

The superior mesenteric lymph-glands receive afferents from the jejunum, ileum, cæcum, vermiform process, and the ascending and transverse parts of the colon; their efferents pass to the superior mesenteric group of pre-aortic lymph-glands.

The inferior mesenteric lymph-glands (fig. 704) consist of: (a) small glands on the branches of the left colic and sigmoid arteries; (b) a group in the sigmoid mesocolon, around the superior hæmorrhoidal artery; and (c) a *pararectal* group in contact with the muscular coat of the rectum. They drain the descending and sigmoid parts of the colon and the upper part of the rectum; their efferents pass to the inferior mesenteric group of pre-aortic lymph-glands.

LYMPHATIC VESSELS OF THE ABDOMEN AND PELVIS

The lymphatic vessels of the abdomen and pelvis may be divided into 1. parietal and 2. visceral.

1. The **parietal lymphatic vessels** consist of two sets, superficial and deep.

The *superficial lymphatic vessels* follow the course of the superficial blood-vessels, and converge to the superficial inguinal lymph-glands; those derived

FIG. 703—The lymphatics of the cæcum and vermiform process, from behind.
(Jamieson and Dobson.)

from the skin of the front of the abdomen below the umbilicus follow the course of the superficial epigastric vessels, and those from the sides of the lumbar part of the abdominal wall pass along the crest of the ilium, with the superficial iliac circumflex vessels. The superficial lymphatic vessels of the gluteal region turn horizontally round the buttock, and join the superficial inguinal and subinguinal lymph-glands.

The *deep lymphatic vessels* run alongside the principal blood-vessels. Those of the parietes of the pelvis, which accompany the superior and inferior gluteal

and obturator vessels, follow the course of the hypogastric artery, and ultimately join the lateral aortic lymph-glands.

Lymphatic vessels of the perinæum and external genitals.—The lymphatic vessels of the perinæum, of the skin of the penis, and of the scrotum (or vulva) follow the course of the external pudendal vessels, and end in the superficial inguinal and subinguinal lymph-glands. Those of the glans penis (vel clitoridis) terminate partly in the deep subinguinal lymph-glands and partly in the external iliac lymph-glands.

2. The **visceral lymphatic vessels** consist of: (1) those of the sub-diaphragmatic portion of the digestive tube and its associated glands, the

FIG. 704.—Lymphatics of colon. (Jamieson and Dobson.)

Inferior mesenteric lymph-glands

liver and pancreas; (2) those of the spleen and suprarenal glands; (3) those of the urinary organs; (4) those of the reproductive organs.

(1) The *lymphatic vessels of the subdiaphragmatic portion of the digestive tube* are situated partly in the mucous membrane and partly in the sero-muscular coats, but as the former system drains into the latter, the two may be considered as one.

The *lymphatic vessels of the stomach* (figs. 700, 701) are continuous at the cardiac orifice with those of the œsophagus, and at the pylorus with those of the duodenum. They mainly follow the blood-vessels, and may be arranged in four sets. The first set accompanies the branches of the left gastric artery, receives tributaries from a large area on either surface of the stomach, and terminates in the superior gastric lymph-glands. Those of the second set drain the fundus and body of the stomach on the left of a line drawn vertically from the œsophagus; they accompany, more or less closely, the short gastric and left gastro-epiploic arteries, and end in the pancreaticocolic lymph-glands.

The third set drains the right part of the greater curvature as far as the pyloric portion, and ends in the inferior gastric lymph-glands, the efferents of which pass to the subpyloric group. Those of the fourth set drain the pyloric portion and pass to the hepatic, subpyloric, and superior gastric lymph-glands.

The *lymphatic vessels of the duodenum* consist of an anterior and a posterior set, which open into a series of small *pancreaticoduodenal lymph-glands*, on the anterior and posterior aspects of the groove between the head of the pancreas and the duodenum. The efferents of these glands run in two directions, upwards to the hepatic lymph-glands, and downwards to the pre-aortic lymph-glands around the origin of the superior mesenteric artery.

The *lymphatic vessels of the jejunum and ileum* are termed *lacteals*, from the milk-white fluid they contain during intestinal digestion. They run between the layers of the mesentery and enter the mesenteric glands, the efferents from which end in the pre-aortic lymph-glands.

The *lymphatic vessels of the vermiform process and cæcum* (figs. 702, 703) are numerous, since in the wall of the vermiform process there is a large amount of adenoid tissue. From the body and tail of the vermiform process eight to fifteen vessels ascend between the layers of the mesenteriole, one or two being interrupted in the lymph-gland which lies between the layers of this peritoneal fold. They unite to form three or four vessels, which end partly in the lower and partly in the upper lymph-glands of the ileocolic chain. The vessels from the root of the vermiform process and from the cæcum consist of an anterior and a posterior group. The anterior vessels pass in front of the cæcum, and end in the anterior ileocolic lymph-glands and in the upper and lower lymph-glands of the ileocolic chain; the posterior vessels ascend over the back of the cæcum and terminate in the posterior ileocolic lymph-glands and in the lower lymph-glands of the ileocolic chain.

Lymphatic vessels of the colon (fig. 704).—The lymphatic vessels of the ascending and transverse parts of the colon end in the mesenteric lymph-glands, after traversing the right colic and mesocolic lymph-glands. Those of the descending and sigmoid parts of the colon are interrupted by the small lymph-glands on the branches of the left colic and sigmoid arteries, and ultimately end in the pre-aortic lymph-glands around the origin of the inferior mesenteric artery.

Lymphatic vessels of the anus, anal canal, and rectum.—The lymphatics from the *anus* pass forwards and end with those of the integument of the perinæum and scrotum in the superficial inguinal lymph-glands; those from the *anal canal* accompany the middle and inferior hæmorrhoidal arteries, and end in the hypogastric lymph-glands; while those from the *rectum* traverse the pararectal lymph-glands and pass to the lymph-glands in the sigmoid mesocolon; the efferents from the latter terminate in the pre-aortic lymph-glands around the origin of the inferior mesenteric artery.

The *lymphatic vessels of the liver* are divisible into two sets, superficial and deep. The former arise in the subperitoneal areolar tissue over the entire surface of the organ, and may be grouped into: (a) those on the convex surface, (b) those on the inferior surface.

(a) On the *convex surface*.—The vessels from the back part of this surface reach their terminal lymph-glands by three different routes: the vessels of the middle set, five or six in number, pass through the vena-caval foramen in the Diaphragm and end in one or two lymph-glands which are situated around the terminal part of the inferior vena cava; a few vessels from the left side pass backwards towards the oesophageal hiatus, and terminate in the paracardial group of superior gastric lymph-glands; the vessels from the right side, one or two in number, run on the abdominal surface of the Diaphragm, and, after crossing its right crus, end in the pre-aortic lymph-glands which surround the origin of the coeliac artery. From the portions of the right and left lobes adjacent to the falciform ligament, the lymphatic vessels converge to form two trunks, one of which accompanies the inferior vena cava through the Diaphragm, and ends in the lymph-glands around the terminal part of this vessel; the other runs downwards and forwards, and, turning round the anterior sharp margin of the liver, accompanies the upper part of the ligamentum teres, and ends in the upper hepatic lymph-glands. From the anterior surface a few additional vessels turn round the anterior sharp margin to reach the upper hepatic lymph-glands.

(b) On the *inferior surface*.—The vessels from this surface mostly converge to the porta hepatis, and accompany the deep lymphatics emerging from the porta to the hepatic lymph-glands; one or two from the posterior parts of the right and caudate lobes accompany the inferior vena cava through the Diaphragm, and end in the lymph-glands round the terminal part of this vein.

The deep lymphatics converge to ascending and descending trunks. The ascending trunks accompany the hepatic veins and pass through the Diaphragm to end in the lymph-glands round the terminal part of the inferior vena cava. The descending trunks emerge from the porta hepatis, and end in the hepatic lymph-glands.

The *lymphatic vessels of the gall-bladder* pass to the cystic lymph-gland and to the hepatic lymph-glands in the porta hepatis; those of the *common bile-duct* to the hepatic lymph-glands alongside the duct and to the upper pancreaticoduodenal lymph-glands.

FIG. 705.—Lymphatics of the urinary bladder. (Cunéo and Marcille.)

The *lymphatic vessels of the pancreas* follow the course of its blood-vessels. Most of them enter the pancreaticocolic lymph-glands, but some end in the pancreaticoduodenal lymph-glands, and others in the pre-aortic lymph-glands near the origin of the superior mesenteric artery.

(2) The *lymphatic vessels of the spleen and suprarenal glands*.

The *lymphatic vessels of the spleen*, both superficial and deep, accompany the splenic blood-vessels and pass to the pancreaticocolic lymph-glands.

The *lymphatic vessels of the suprarenal glands* usually accompany the suprarenal veins, and end in the lateral aortic lymph-glands; occasionally some of them pierce the crura of the Diaphragm and end in the lymph-glands of the posterior mediastinal cavity.

(3) The *lymphatic vessels of the urinary organs*.

The *lymphatic vessels of the kidney* form three plexuses: one in the substance of the kidney, a second beneath its fibrous capsule, and a third in the perinephric fat; the second and third communicate freely with each other.

The vessels from the plexus in the substance of the kidney converge to form four or five trunks which issue at the hilum. Here they are joined by vessels from the plexus under the capsule, and, following the course of the renal vein,

end in the lateral aortic lymph-glands. The perinephric plexus is drained directly into the upper lateral aortic lymph-glands.

The *lymphatic vessels of the ureter* run in different directions. Those from its upper portion end partly in the efferent vessels from the kidney and partly in the lateral aortic lymph-glands; those from the portion immediately above the brim of the lesser pelvis are drained into the common iliac lymph-glands; while the vessels from the intrapelvic portion of the tube either join the efferents from the bladder, or end in the hypogastric lymph-glands.

FIG. 706.—Lymphatics of the prostate. (Cunéo and Marcille.)

a, b. External iliac lymph-glands. *c.* Vessel draining into external iliac lymph-glands. *d.* Retro-prostatic lymph-glands. *e.* Vessels draining into lymph-gland on sacral promontory. *f.* Lymph-gland in front of sacral promontory. *g.* Lateral sacral lymph-glands. *h.* Middle haemorrhoidal lymphatic vessels. *i.* Middle haemorrhoidal lymphatic vessels.

The *lymphatic vessels of the urinary bladder* (fig. 705) begin in two plexuses, an intra- and an extra-muscular, it being generally admitted that the mucous membrane is devoid of lymphatics.* The efferent vessels are arranged in two groups, one from the anterior and another from the posterior surface of the bladder. The vessels from the *anterior* surface pass to the external iliac lymph-glands, but in the course of these vessels minute lymph-glands are situated. These minute lymph-glands are arranged in two groups, an *anterior vesical*, in

* Some authorities maintain that a plexus of lymphatic vessels does exist in the mucous membrane of the bladder (consult *Médecine opératoire des Voies urinaires*, par J. Albarran, Paris, 1909).

front of the bladder, and a *lateral vesical*, in relation to the lateral umbilical ligament. The vessels from the *posterior* surface pass to the hypogastric, external, and common iliac lymph-glands; those draining the upper part of this surface traverse the lateral vesical lymph-glands.

The *lymphatic vessels of the prostate* (fig. 706) terminate chiefly in the hypogastric and sacral lymph-glands, but one trunk from the posterior surface ends in the external iliac lymph-glands, and another from the anterior surface joins the vessels which drain the membranous part of the urethra.

FIG. 707.—Lymphatics of the uterus. (Cunéo and Marcille.)

a. Efferents to lateral aortic lymph-glands. *b, c, d.* Efferents to external iliac lymph-glands. *e.* Network on lateral aspect of cervix uteri. *f.* Lymph-glands in front of sacral promontory. *g.* Efferents to lymph-glands in front of sacral promontory. *h.* Hypogastric lymph-glands. *i.* Lateral sacral lymph-glands. *j.* Vessels draining into hypogastric lymph-glands. *k.* Vessels passing to lateral sacral lymph-glands.

Lymphatic vessels of the urethra.—The lymphatics of the *cavernous* portion of the urethra accompany those of the glans penis, and end with them in the superficial and deep subinguinal and external iliac lymph-glands. Those of the *membranous* and *prostatic* portions, and those of the whole urethra in the female, pass to the hypogastric lymph-glands.

(4) *The lymphatic vessels of the reproductive organs.*

The lymphatic vessels of the testis consist of two sets, superficial and deep, the former commencing on the surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form from four to eight collecting trunks which ascend with the testicular veins in the spermatic cord and along the front of the Psoas major, and end in the lateral and pre-aortic groups of lumbar lymph-glands.*

* "The Lymphatics of the Testicle," by Jamieson and Dobson, *Lancet*, Feb. 19, 1900.

The *lymphatic vessels of the ductus deferens* pass to the external iliac lymph-glands; those of the *vesiculæ seminales* partly to the hypogastric and partly to the external iliac lymph-glands.

The *lymphatic vessels of the ovary* are similar to those of the testis, and ascend with the ovarian artery to the lateral and pre-aortic lymph-glands.

The *lymphatic vessels of the uterine tube* pass partly with those of the ovary and partly with those of the uterus.

The *lymphatic vessels of the uterus* (fig. 707) consist of two sets, superficial and deep, the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri run in three directions: transversely to the external iliac lymph-glands, posterolaterally to the hypogastric lymph-glands, and posteriorly to the common iliac lymph-glands. The majority of the vessels of the body and fundus of the uterus pass lateralwards in the upper parts of the broad ligaments, and ascend alongside the ovarian vessels to the lateral and pre-aortic lymph-glands; a few, however, run to the external iliac lymph-glands, and one or two run along the round ligament of the uterus to the superficial inguinal lymph-glands. In the unimpregnated uterus the lymphatic vessels are very small, but during gestation they are greatly enlarged.

The *lymphatic vessels of the vagina* are carried in three directions: those of the upper part to the external iliac lymph-glands, those of the middle part to the hypogastric lymph-glands, and those of the lower part to the common iliac lymph-glands. On the course of the vessels from the middle and lower parts small lymph-glands are situated. Some lymphatic vessels from the lower part of the vagina join those of the vulva and pass to the superficial inguinal lymph-glands. The lymphatic vessels of the vagina anastomose with those of the cervix uteri, vulva, and rectum, but not with those of the bladder.

FIG. 708.—The right sternal or internal mammary lymph-glands (E. P. Stibbe).

LYMPH-GLANDS OF THE THORAX

The lymph-glands of the thorax may be divided into: 1. parietal and 2. visceral—the former being situated in the thoracic wall, the latter in relation to the viscera.

1. The **parietal lymph-glands** include the sternal, intercostal, and diaphragmatic glands.

(a) The **sternal or internal mammary lymph-glands** are four or five in number on each side, and are placed (fig. 708) at the anterior ends of the intercostal spaces, by the side of the internal mammary artery.* They derive afferents from the mamma, from the deeper structures of the anterior abdominal wall above the level of the umbilicus, from the upper surface of the liver through a small group of lymph-glands which lies behind the xiphoid process, and from the deeper parts of the anterior portion of the thoracic wall. Their efferents usually unite to form a single trunk on either side; this may open directly into the junction of the internal jugular and subclavian veins, or that of the right side may join the right subclavian trunk, and that of the left the thoracic duct.

(b) The **intercostal lymph-glands** lie in the posterior parts of the intercostal spaces and in front of the heads of the ribs. They receive the deep lymphatics from the posterolateral aspect of the chest; some of these vessels are interrupted by small lateral intercostal lymph-glands. The efferents of the lymph-glands in the lower four or five spaces unite to form a trunk, which descends and opens either into the cisterna chyli or into the commencement

* E. P. Stibbe, *Journal of Anatomy*, vol. 52.

of the thoracic duct. The efferents of the lymph-glands in the upper spaces of the left side end in the thoracic duct; those of the corresponding right-spaces, in the right lymphatic duct.

(c) The **diaphragmatic lymph-glands** lie on the thoracic aspect of the Diaphragm, and consist of three sets, anterior, middle, and posterior.

The *anterior* set comprises (a) two or three small lymph-glands behind the base of the xiphoid process, which receive afferents from the convex surface of the liver, and (b) one or two lymph-glands on either side near the junction

FIG. 709.—The tracheobronchial lymph-glands. (From a figure designed by M. Hallé.)

of the seventh rib with its cartilage, which receive lymphatic vessels from the front part of the Diaphragm. The efferent vessels of the anterior set pass to the sternal lymph-glands.

The *middle* set consists of two or three lymph-glands on either side close to where the phrenic nerves enter the Diaphragm. On the right side some of the lymph-glands of this group lie within the fibrous wall of the pericardium, on the front of the termination of the inferior vena cava. The afferents of this set are derived from the middle part of the Diaphragm, those on the right side also receiving afferents from the convex surface of the liver. Their efferents pass to the posterior mediastinal lymph-glands.

The *posterior* set consists of a few lymph-glands situated on the back of the crura of the Diaphragm, and connected on the one hand with the lumbar lymph-glands, and on the other with the posterior mediastinal lymph-glands.

2. The **visceral lymph-glands** consist of three groups, viz. anterior mediastinal, posterior mediastinal, and tracheobronchial.

The anterior mediastinal lymph-glands are placed in the anterior part of the superior mediastinal cavity, in front of the aortic arch and in relation to the innominate veins and the large arterial trunks which arise from the aortic arch. They receive afferents from the thymus and pericardium, and from the sternal lymph-glands; their efferents unite with those of the tracheobronchial lymph-glands, to form the right and left bronchomediastinal trunks.

The posterior mediastinal lymph-glands lie behind the pericardium in relation to the œsophagus and descending thoracic aorta. Their afferents are derived from the œsophagus, the posterior part of the pericardium, the Diaphragm, and the convex surface of the liver. Their efferents mostly end in the thoracic duct, but some join the tracheobronchial lymph-glands.

The tracheobronchial lymph-glands (fig. 709) form four main groups, and include some of the largest lymph-glands in the body: (a) *tracheal*, on either side of the trachea; (b) *bronchial*, in the angles between the lower part of the trachea and bronchi, and in the angle between the two bronchi; (c) *bronchopulmonary*, in the hilum of each lung; and (d) *pulmonary*, in the lung substance, on the larger branches of the bronchi. The afferents of the tracheobronchial lymph-glands drain the lungs and bronchi, the thoracic part of the trachea, and the heart; some of the efferents of the posterior mediastinal lymph-glands also end in this group. Their efferent vessels ascend upon the trachea and unite with efferents of the internal mammary and anterior mediastinal lymph-glands to form the *right* and *left bronchomediastinal trunks*. The right bronchomediastinal trunk may join the right lymphatic duct, and the left the thoracic duct, but more frequently they open independently of these ducts into the junction of the internal jugular and subclavian veins of their own side.

Applied Anatomy.—In all town-dwellers there are continually being swept into these lymph-glands from the bronchi and alveoli large quantities of the dust and black carbonaceous pigment that are so freely inhaled in cities. At first the lymph-glands are moderately enlarged, firm, inky black and gritty on section; later they enlarge still further, often becoming fibrous from the irritation set up by the minute foreign bodies with which they are crammed, and may break down into a soft slimy mass or may calcify. In tuberculosis of the lungs these lymph-glands are practically always infected; they enlarge, being filled with tuberculous deposits that may soften, or become fibrous, or calcify. Not infrequently an enlarged tuberculous lymph-gland perforates into a bronchus, discharging its contents into the tube. When this happens there is great danger of acute pulmonary tuberculosis, the infecting gland-substance being rapidly spread throughout the bronchial system by the coughing its presence in the air-passages excites.

Tuberculous infection with considerable enlargement of the tracheobronchial glands is common in children. It produces a characteristic patch of impaired resonance on percussion, with increase in the vocal fremitus and resonance and harsh bronchial breath-sounds, over a diamond-shaped area on the back about the region of the third, fourth and fifth dorsal vertebral spines. It is thought, too, that enlargement of these glands produces an irritative dry cough in children, by pressure on the pulmonary nerves in their neighbourhood. Enlargement of these glands can best be diagnosed by use of the x-rays, and, it must be remembered, is not by any means always due to infection with tubercle bacilli. ✓

LYMPHATIC VESSELS OF THE THORAX

The lymphatic vessels of the thorax may be divided into: 1. those of the thoracic wall and 2. those of the thoracic viscera.

1. The *superficial lymphatic vessels of the thoracic wall* ramify beneath the skin and converge to the axillary lymph-glands. Those over the Trapezius and Latissimus dorsi run forwards and unite to form about ten or twelve trunks which end in the subscapular group. Those over the pectoral region, including the vessels from the skin covering the peripheral part of the mamma, run backwards, and those over the Serratus anterior upwards, to the pectoral group. Others near the lateral margin of the sternum pass inwards between the rib cartilages and end in the sternal lymph-glands, while the vessels of opposite sides anastomose across the front of the sternum. A few vessels from the upper part of the pectoral region ascend over the clavicle to the supraclavicular group of cervical lymph-glands.

The *lymphatic vessels of the mamma* originate in a plexus in the interlobular spaces and on the walls of the galactophorous ducts. Those from the central part of the mamma pass to an intricate plexus situated beneath the areola, a plexus which receives also the lymphatics from the skin over the central part of the mamma and those from the areola and nipple. Its efferents are collected into two trunks which pass to the pectoral group of axillary lymph-glands. The vessels which drain the medial part of the mamma pierce the thoracic wall and end in the sternal lymph-glands, while a vessel occasionally emerges from the upper part of the mamma and, piercing the Pectoralis major, terminates in the subclavicular lymph-glands (fig. 694).

The *deep lymphatic vessels of the thoracic wall* consist of :

(a) The lymphatics of the muscles which lie on the ribs : most of these end in the axillary lymph-glands, but some from the Pectoralis major pass to the sternal lymph-glands. (b) The intercostal lymphatic vessels which drain the Intercostales and parietal pleura. Those draining the Intercostales externi run backwards and, after receiving the vessels which accompany the posterior branches of the intercostal arteries, end in the intercostal lymph-glands. Those of the Intercostales interni and parietal pleura consist of a single trunk in each space. These trunks run forwards in the subpleural tissue and the upper six open separately into the sternal lymph-glands or into the vessels which unite them : those of the lower spaces unite to form a single trunk which terminates in the lowest of the sternal lymph-glands. (c) The *lymphatic vessels of the Diaphragm* which form two plexuses, one on its thoracic and another on its abdominal surface ; these plexuses anastomose freely with each other, and are best marked on the parts covered respectively by the pleuræ and peritoneum. That on the thoracic surface communicates with the lymphatics of the costal and mediastinal parts of the pleura, and its efferents consist of three groups : anterior, passing to the lymph-glands which lie near the junction of the seventh rib with its cartilage ; middle, to the lymph-glands on the œsophagus and to those around the termination of the inferior vena cava ; and posterior, to the lymph-glands which surround the aorta at the point where this vessel leaves the thoracic cavity. The plexus on the abdominal surface is composed of fine vessels, and anastomoses with the lymphatics of the liver and, at the periphery of the Diaphragm, with those of the sub-peritoneal tissue. The efferents from the right half of this plexus terminate partly in a group of lymph-glands on the trunk of the corresponding inferior phrenic artery, while others end in the right lateral aortic lymph-glands. Those from the left half of the plexus pass to the pre-aortic and lateral aortic lymph-glands and to the lymph-glands on the terminal portion of the œsophagus.

2. The *lymphatic vessels of the thoracic viscera* comprise those of the heart and pericardium, lungs and pleura, thymus, and œsophagus.

The *lymphatic vessels of the heart* consist of two plexuses : (a) deep, immediately under the endocardium, and (b) superficial, subjacent to the visceral pericardium. The deep plexus opens into the superficial, the efferents of which form left and right collecting trunks. The *left* trunks, two or three in number, ascend in the anterior longitudinal sulcus, receiving, in their course, vessels from both ventricles. On reaching the coronary sulcus they are joined by a large trunk from the diaphragmatic surface of the heart, and then unite to form a single vessel which ascends between the pulmonary artery and the left atrium and ends in one of the tracheobronchial lymph-glands. The *right* trunk receives its afferents from the right atrium and from the right border and diaphragmatic surface of the right ventricle. It ascends in the posterior longitudinal sulcus and then runs forward in the coronary sulcus, and passes up behind the pulmonary artery, to end in one of the tracheobronchial lymph-glands.

The *lymphatic vessels of the lungs* originate in two plexuses, a superficial and a deep. The superficial plexus is placed beneath the pulmonary pleura ; the deep accompanies the branches of the pulmonary vessels and the ramifications of the bronchi. In the case of the larger bronchi the deep plexus consists of two networks—a submucous, beneath the mucous membrane, and a peribronchial, outside the walls of the bronchi. In the smaller bronchi there is but a single plexus, which extends as far as the bronchioles, but fails to reach the alveoli, in the walls of which there are no traces of lymphatic

vessels. The superficial efferents turn round the borders of the lungs and the margins of their fissures, and converge to end in some lymph-glands situated at the hilum; the deep efferents are conducted to the hilum along the pulmonary vessels and bronchi, and end in the tracheobronchial lymph-glands. Little or no anastomosis occurs between the superficial and deep lymphatics of the lungs, except in the region of the hilum.

The *lymphatic vessels of the pleura* consist of two sets—one in the visceral and another in the parietal part of the membrane. Those of the visceral pleura drain into the superficial efferents of the lung, while those of the parietal pleura have three modes of ending, viz.: (a) those of the costal portion join the lymphatics of the Intercostales interni and so reach the sternal lymph-glands; (b) those of the diaphragmatic part are drained by the efferents of the Diaphragm; while (c) those of the mediastinal portion end in the posterior mediastinal lymph-glands.

The *lymphatic vessels of the thymus* end in the anterior mediastinal, tracheobronchial, and sternal lymph-glands.

The *lymphatic vessels of the œsophagus* form a plexus round that tube, and the collecting vessels from the plexus drain into the posterior mediastinal lymph-glands.

NEUROLOGY

THE nervous system is the most complicated and highly organised of the various systems which make up the human body. It is built up of nervous and non-nervous tissues—the former consisting of nerve-cells and nerve-fibres, the latter of neuroglia and blood-vessels, together with certain enveloping membranes.

An outline of the development of the nervous system is given on pp. 85 to 109, and the minute structure of the nervous elements and neuroglia is described on pp. 34 to 40.

The nervous system is usually divided, for descriptive purposes, into the cerebrospinal and sympathetic systems, but this division is an arbitrary one, for the two are intimately connected.

The **cerebrospinal system** is composed of a central and a peripheral part. The *central part* consists of an upper expanded portion, the *encephalon* or *brain*, which is contained within the cranium, and a lower, elongated, cylindrical portion, the *medulla spinalis* or *spinal cord*, which is lodged in the vertebral canal. The two portions are continuous with one another at the level of the upper border of the atlas vertebra, and together constitute the *central nervous system* or *cerebrospinal axis*. The *peripheral part* consists of a series of cerebrospinal nerves which unite the central nervous system to the various parts of the body, and are associated with the functions of the special and general senses, and with the voluntary movements of the body. These nerves are forty-three in number on either side—twelve *cerebral*, attached to the brain, and thirty-one *spinal*, to the medulla spinalis.

The **sympathetic nervous system** transmits impulses which bring about the constriction of the arteries, regulate the movements of the viscera and iris (in association with certain cerebrospinal nerves), stimulate the arrectores pilorum muscles, and excite the secretion of the sudoriferous glands. It comprises two rows of *central ganglia*, one on either side of the middle line in front of the vertebral column, the ganglia of each row being united by vertical strands of nerve-fibres, so as to constitute a pair of knotted cords, named the *sympathetic trunks*. These trunks reach from the base of the skull to the coccyx and are connected to the medulla spinalis and spinal nerves by what are termed white and grey rami communicantes. Nerves issue from the ganglia of the sympathetic trunks and form three great prevertebral plexuses which supply the thoracic, abdominal and pelvic viscera; in relation with the walls of the viscera intricate nerve-plexuses and numerous *peripheral ganglia* are found.

The *white rami communicantes* consist of fine medullated fibres which originate in the cells of the lateral grey column of the medulla spinalis, and pass through the thoracic and the first and second lumbar nerves to the ganglia of the sympathetic trunk. These fibres are named *preganglionic*, and end by forming synapses around the cells of the sympathetic ganglia, while from the cells of these ganglia other fibres, termed *postganglionic*, and which are usually non-medullated, arise. Some of the postganglionic fibres pass directly, or through the prevertebral plexuses, to the involuntary muscles of the vessels and viscera, while others run, in the *grey rami communicantes*, from the ganglia of the sympathetic trunk to all the spinal nerves; by these nerves they are conveyed to the blood-vessels, sudoriferous glands and arrectores pilorum muscles.

The preganglionic fibres do not all terminate in the ganglia of the sympathetic trunks. Some, as will be described later, run through these ganglia to cell-stations associated with the prevertebral plexuses.

Fine medullated nerve-fibres, homologous with those which go from the medulla spinalis to the sympathetic trunks, issue from (a) certain cerebral nerves (e.g. oculomotor, facial, glossopharyngeal, vagus and accessory), and (b) from the second, third and fourth sacral nerves. These fibres do not join the sympathetic trunks, but terminate in peripheral ganglia, from the cells of which fibres pass to be distributed to secreting glands or involuntary muscle. These nerves, together with those of the sympathetic system, are termed by physiologists *autonomic nerves*. The distinguishing characteristics of all autonomic nerves are: (1) they consist of preganglionic medullated fibres originating in the central nervous system, and postganglionic fibres, usually non-medullated, arising in the ganglia, and (2) they are distributed to structures whose activity is involuntary.

STRUCTURE OF THE PERIPHERAL NERVES AND GANGLIA

The **cerebrospinal nerves** consist of numerous nerve-fibres collected together and enclosed in membranous sheaths (fig. 710). A small bundle of fibres, enclosed

FIG. 710.—Transverse section of a part of a human tibial nerve. $\times 50$.

in a tubular sheath, is called a *funiculus*; if the nerve be small, it may consist of only a single funiculus; but if large, it consists of several funiculi held together and invested by connective tissue; this investment is known as the *epineurium*. Each funiculus is surrounded by a distinct sheath, the *perineurium*; this consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it is made up of connective tissue, which has a lamellar arrangement. The nerve-fibres are held together and supported within the funiculus by delicate connective tissue called the *endoneurium*; it is continuous with septa which pass inwards from the innermost layer of the perineurium, and shows a ground substance in which are imbedded fine bundles of fibrous connective tissue running for the most part longitudinally. The cerebrospinal nerves consist almost exclusively of medullated nerve-fibres, only a very small proportion of non-medullated fibres being present.

The blood-vessels supplying a nerve end in a minute capillary plexus, the vessels composing which pierce the perineurium, and run, for the most part, parallel with the fibres; they are connected together by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine non-medullated nerve-fibres, *vasomotor fibres*, accompany these vessels, and break up into elementary fibrils which form a network around them. Horsley has demonstrated certain medullated fibres running in the epineurium and terminating in small spheroidal tactile corpuscles or end-bulbs of Krause. These nerve-fibres, which Marshall believes to be sensory, and which he has termed *nervi nervorum*, are considered by him to have an important bearing upon certain neuralgic pains.

The nerve-fibres pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component funiculi, it may be seen that bundles of fibres from one funiculus occasionally join, at a very acute angle, another funiculus proceeding in the same direction; from this, branches are given off, to join again in like manner with other funiculi.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighbouring nerve. The communications which thus take place form what is called a *plexus*. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal funiculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus, the component nerves divide, then join, and again subdivide in such a complex manner that the individual funiculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from all the primary nerves' trunks entering the plexus. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the funiculi and primitive fibres. In each case, however, the individual fibres remain separate and distinct.

It is probable that, through this interchange of fibres, every branch passing off from a plexus has a more extensive connexion with the medulla spinalis than if it had proceeded to its distribution without forming connexions with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nervous centres; by this means, also, groups of muscles may be associated for combined action.

The **sympathetic nerves** consist largely of non-medullated fibres, collected in funiculi and enclosed in sheaths of connective tissue. There is, however, in these nerves a certain admixture of medullated fibres; thus, the cervical portions of the sympathetic trunk and the splanchnic nerves contain many medullated preganglionic fibres.

The cerebrospinal and sympathetic nerve-fibres convey various impressions. The *sensory* nerves, called also *centripetal* or *afferent* nerves, transmit to the nervous centres impressions made upon the peripheral extremities of the nerves, and in this way the mind, through the medium of the brain, becomes conscious of external objects. The *centrifugal* or *efferent* nerves transmit impressions from the nervous centres to the parts to which the nerves are distributed, these impressions either exciting muscular contraction, or influencing the process of secretion and possibly the processes of nutrition and growth.

Origins of nerves.—The origin of a nerve is in some cases single—that is to say, the whole nerve emerges from the nervous centre by a single root; in other instances the nerve arises by two or more roots which leave different parts of the nerve-centre, sometimes widely apart from each other. The point where the nerve-root or roots emerge from the surface of the nervous centre is named the *superficial* or *apparent* origin, but the fibres of the nerve can be traced for a certain distance into the substance of the nervous centre to some portion of the grey substance, which constitutes the *deep* or *real* origin of the nerve. The centrifugal or efferent nerve-fibres originate in the nerve-cells of the grey substance, the axis-cylinder processes of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the fibres spring from nerve-cells in the organs of special sense (e.g. the retina) or from nerve-cells in the ganglia. Having entered the nerve-centre they branch and send their ultimate twigs among its cells, without, however, uniting with them.

Peripheral terminations of nerves.—Nerve-fibres terminate peripherally in various ways, and these may be conveniently studied in the sensory and motor

nerves respectively. The terminations of the sensory nerves are dealt with in the section on sense-organs.

Motor nerves can be traced to muscular fibres either unstriated or striated. In the *unstriated* or *involuntary muscles* the nerves divide into numerous branches, which communicate and form fine plexuses. At the junctions of the branches small nucleated bodies (ganglion-cells) are situated. From the plexuses minute branches are given off, which divide and break up into the ultimate fibrils of which the nerves are composed. These fibrils course between the involuntary muscle-cells, and, according to Elischer, terminate on the surfaces of the cells, opposite the nuclei, in minute swellings.

In the *striated* or *voluntary muscle* the nerves enter the sheath of the muscle, break up into fibres or bundles of fibres which form plexuses, and gradually divide until, as a rule, a single nerve-fibre enters a single muscular fibre; if the muscular fibre be long, more than one nerve-fibre may enter it. Within the muscular fibre the nerve terminates in a special expansion, called by Kühne, who first accurately described it, a *motor end-plate* (fig. 711). The nerve-fibre, on approaching the

Fig. 711.—Muscular fibres of *Lacerta viridis* with the terminations of nerves.

a. Seen in profile. P P. The nerve end-plates. S S. The base of the plate, consisting of a granular mass with nuclei. b. The same as seen in looking at a perfectly fresh fibre, the nerve-ends being probably still excitable. (The forms of the variously divided plate can hardly be represented in a woodcut by sufficiently delicate and pale contours to reproduce correctly what is seen in Nature.) c. The same as seen two hours after death from poisoning by curare.

muscular fibre, suddenly loses its medullary sheath, the neurolemma becomes continuous with the sarcolemma of the muscle, and only the axis-cylinder enters the muscular fibre. There it at once spreads out, ramifying like the roots of a tree, immediately beneath the sarcolemma, and becomes imbedded in a layer of granular matter, containing a number of clear, oblong nuclei, the whole constituting an end-plate from which the contractile wave of the muscular fibre is said to start.

Ganglia are small aggregations of nerve-cells. They are found on the posterior roots of the spinal nerves; on the sensory roots of the trigeminal, facial, glossopharyngeal, and vagus nerves, and on the acoustic nerves. They are also found in connexion with the sympathetic nerves. On section they are seen to consist of a reddish-grey substance, traversed by numerous white nerve-fibres; they vary considerably in form and size; the largest are found in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. Each ganglion is invested by a smooth and firm, closely adhering, membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion.

In structure all ganglia are essentially similar, consisting of the same structural elements—viz. nerve-cells and nerve-fibres. Each nerve-cell has a nucleated sheath which is continuous with the neurolemma of the nerve-fibre with which the cell is connected. The nerve-cells in the ganglia of the spinal nerves (fig. 712) are pyriform in shape, and each has a single process which acquires a medullary sheath soon after leaving the cell. The process runs towards the centre of the ganglion, and divides in a T-shaped manner, one limb of the cross-bar entering the medulla

spinalis, the other limb passing outwards to the periphery. In the sympathetic ganglia (fig. 713) the nerve-cells are multipolar and each has one axis-cylinder process and several dendrons; the axon emerges from the ganglion as a non-medullated nerve-fibre. The spinal and sympathetic ganglia differ somewhat

FIG. 712.—Transverse section of a spinal ganglion of a rabbit.

A. Ganglion $\times 20$. a. Large clear nerve-cell; b. small deeply staining nerve-cell; c. nuclei of capsule $\times 350$. The lines in the centre point to the corresponding cells in the ganglion.

in the size and disposition of the cells and in the number of nerve-fibres entering and leaving them. In the spinal ganglia (fig. 712) the nerve-cells are much larger and for the most part collected in groups near the periphery, while the fibres, which are mostly medullated, traverse the central portion of the ganglion; whereas in the sympathetic ganglia (fig. 713) the cells are smaller and distributed in irregular groups throughout the whole ganglion; the fibres also are irregularly scattered; some of those entering are medullated, while many leaving the ganglion are non-medullated.

Neuron theory.—The nerve-cell and its processes collectively constitute what is termed a *neuron*, and Waldeyer formulated the theory that the nervous system is built up of numerous neurons, 'anatomically and genetically independent of one another.' According to this *neuron theory* the processes of one neuron only come into contact, and are never in direct continuity, with those of other neurons; impulses being transmitted from one nerve-cell to another through the points of contact. This theory is based on the following facts, viz.: (1) embryonic nerve-cells or neuroblasts are entirely distinct from one another; (2) when nervous tissues are stained by the Golgi method no continuity is seen even between neighbouring neurons; and (3) when degenerative changes occur in nervous tissue, either as the result of disease or experiment, they never spread from one neuron to another, but are limited to the individual neurons, or groups of neurons, primarily affected. It must, however, be added that the validity of the neuron theory has been called in question by certain eminent histologists, who maintain that by the employment of more delicate histological methods, minute fibrils can be followed from one nerve-cell into another.

THE MEDULLA SPINALIS OR SPINAL CORD

The **medulla spinalis** or **spinal cord** is the elongated, nearly cylindrical, part of the central nervous system which occupies the upper two-thirds of the vertebral canal. Its average length in the male is 45 cm.; its weight is about 30 gms. It extends from the level of the upper border of the atlas vertebra to that of the lower border of the first, or upper border of the second, lumbar vertebra. Above, it is continuous with the brain; below, it ends in the *conus medullaris*, from the apex of which a delicate non-nervous filament, the *filum terminale*, descends as far as the first segment of the coccyx (fig. 714).

The position of the medulla spinalis varies with the movements of the vertebral column, its lower extremity being raised slightly when the column is flexed. It also varies at different periods of life: up to the third month of fetal life the medulla spinalis is as long as the vertebral canal, but from this stage onwards the vertebral column grows in length more rapidly than the medulla spinalis, so that by the end of the fifth month the lower end of the medulla spinalis is at the base of the sacrum, and at birth about the third lumbar vertebra. In the early embryo the nerve-roots pass transversely outwards to their respective intervertebral foramina, but owing to the relative inequality in the rates of growth of the medulla spinalis and vertebral column, the nerve-roots become more and more oblique in direction, so that in the adult the lumbar and sacral nerves descend almost vertically to reach their foramina. From the appearance these nerves present at their attachment to the medulla spinalis and from their great length they are collectively termed the *cauda equina* (fig. 716).

The medulla spinalis is ensheathed by three protective membranes which are separated from each other by concentric spaces. The membranes are named from without inwards the *dura mater*, the *arachnoid*, and the *pia mater* (fig. 715). The *dura mater*, a strong, fibrous membrane, forms a wide, tubular sheath which extends below the termination of the medulla spinalis and ends in a pointed cul-de-sac at the level of the lower border of the second sacral vertebra. The *dura mater* is separated from the wall of the vertebral canal by the *epidural cavity*, which contains a quantity of areolar tissue, fat, and a plexus of veins; between the *dura mater* and the subjacent *arachnoid* is the *subdural cavity*, a capillary interval containing a small quantity of fluid, probably of the nature of lymph. The *arachnoid* is a thin, transparent sheath, and is separated from the *pia mater* by the *subarachnoid cavity*, filled with cerebrospinal fluid. The *pia mater* closely invests the medulla spinalis and sends delicate septa into its substance; from each lateral surface of the *pia mater* a fibrous band, named the *ligamentum denticulatum*, projects into the subarachnoid space, and is attached by a series of pointed processes to the inner surface of the *dura mater*.

Thirty-one pairs of spinal nerves spring from the medulla spinalis, each

FIG. 714.—Sagittal section of the vertebral canal to show the lower end of the medulla spinalis and the *filum terminale*. (Testut.)

nerve having an anterior and a posterior root, the latter being distinguished by the presence of an oval swelling, the *spinal ganglion*, which contains numerous nerve-cells. Each root consists of several bundles of nerve-fibres, and at its attachment extends for some distance along the side of the medulla spinalis. The pairs of spinal nerves are grouped as follows: cervical 8, thoracic 12, lumbar 5, sacral 5, coccygeal 1, and, for convenience of description, the medulla spinalis is divided into cervical, thoracic, lumbar, and sacral regions, corresponding with the attachments of the different groups of nerves.

Although no trace of transverse segmentation is visible on the surface of the medulla spinalis, it is convenient to regard it as being built up of a series of superimposed *spinal segments* or *neuromeres*, each of which has a length equivalent to the extent of attachment of a pair of spinal nerves. Since the extent of attachment of the successive pairs of nerves varies in different parts, it follows that the spinal segments are of varying lengths; thus, in the cervical region they average 13 mm., in the mid-thoracic region 26 mm., while in the lumbar and sacral regions they diminish rapidly from 15 mm. at the level of the first pair of lumbar nerves to 4 mm. opposite the attachments of the lower sacral nerves.

FIG. 715.—Diagrammatic transverse section of the medulla spinalis and its membranes.

The *filum terminale* (figs. 714, 716) is a delicate filament, about 20 cm. in length, prolonged downwards from the apex of the conus medullaris. Its upper part, or *filum terminale internum*, about 15 cm. long, is contained within the tubular sheath of dura mater and reaches as far as the lower border of the second sacral vertebra. It is surrounded by the nerves forming the cauda equina, but can be readily distinguished from them by its bluish-white colour. Its lower part, or *filum terminale externum*, is closely invested by, and adherent to, the dura mater; it descends from the apex of the tubular sheath of dura mater and is attached to the back of the first segment of the coccyx. The *filum terminale* consists mainly of fibrous tissue, continuous above with that of the pia mater, but adhering to its outer surface are a few strands of nerve-fibres which probably represent rudimentary second and third coccygeal nerves; further, the central canal of the medulla spinalis is continued downwards into it for 5 or 6 cm.

Enlargements.—The medulla spinalis is not quite cylindrical, being slightly flattened from before backwards; it also presents two swellings or enlargements, an upper or cervical, and a lower or lumbar (fig. 717).

The *cervical enlargement* is the more pronounced, and corresponds with the attachments of the large nerves of the upper limbs. It extends from about the third cervical to the second thoracic vertebra, its maximum circumference (about 38 mm.) being at the level of the attachment of the sixth pair of cervical nerves.

To the *lumbar enlargement* are attached the nerves of the lower limbs. It begins at the level of the ninth thoracic vertebra, and reaches its maximum circumference, of about 33 mm., opposite the last thoracic vertebra, below which it tapers rapidly into the conus medullaris.

Fissure and sulci (fig. 718).—An anterior median fissure and a posterior median sulcus incompletely divide the medulla spinalis into two symmetrical parts, which are joined across the middle line by a commissural band of nervous matter.

The *anterior median fissure* has an average depth of about 3 mm., but is deepest in the lower part of the medulla spinalis. It contains a double fold of pia mater, and its floor is formed by a transverse band of white substance, the *anterior white commissure*, which is perforated by blood-vessels on their way to or from the central part of the medulla spinalis.

FIG. 716.—The cauda equina and filum terminale seen from behind. The dura mater has been opened and spread out, and the arachnoid has been removed.

FIG. 717.—Diagrams of the medulla spinalis.

The *posterior median sulcus* is very shallow; from it a septum of neuroglia reaches rather more than half-way into the substance of the medulla spinalis; this septum varies in depth from 4 to 6 mm., but diminishes considerably in the lower part of the medulla spinalis.

On either side of the posterior median sulcus, and at a short distance from it, the posterior nerve-roots are attached along a vertical furrow named the *posterolateral sulcus*. The portion of the medulla spinalis which lies between this and the posterior median septum is named the *posterior funiculus*. In the cervical and upper thoracic regions the surface of this funiculus presents a longitudinal furrow, the *postero-intermediate sulcus*: this marks the position of a septum which extends into the posterior funiculus and subdivides it into two fasciculi—a medial, named the *fasciculus gracilis* (tract of Coll); and a lateral, the *fasciculus cuneatus* (tract of Burdach) (fig. 724).

FIG. 718.—Transverse section of the medulla spinalis in the mid-thoracic region.

The portion of the medulla spinalis between the posterolateral sulcus and the anterior median fissure is termed the *anterolateral region*. The anterior nerve-roots, unlike the posterior, are not attached in linear series, and their positions of exit are not marked by a sulcus; they arise by separate bundles which spring from the anterior column of grey substance and, passing forward through the white substance, emerge over an area of some width. The most lateral of these bundles is generally taken as a dividing line which separates the anterolateral region into two parts, viz. an *anterior funiculus*, between the anterior median fissure and the most lateral of the anterior nerve-roots; and a *lateral funiculus*, between the exit of these roots and the posterolateral sulcus. In the upper part of the cervical region a series of nerve-roots passes outwards through the lateral funiculus of the medulla spinalis; these unite to form the spinal portion of the accessory nerve, which runs upwards and enters the cranial cavity through the foramen magnum.

INTERNAL STRUCTURE OF THE MEDULLA SPINALIS

The medulla spinalis is composed of grey and white nervous substance, the former being enclosed within the latter (fig. 718).

Grey substance.—The grey substance consists of two symmetrical portions, one in either half of the medulla spinalis: these are joined across the middle

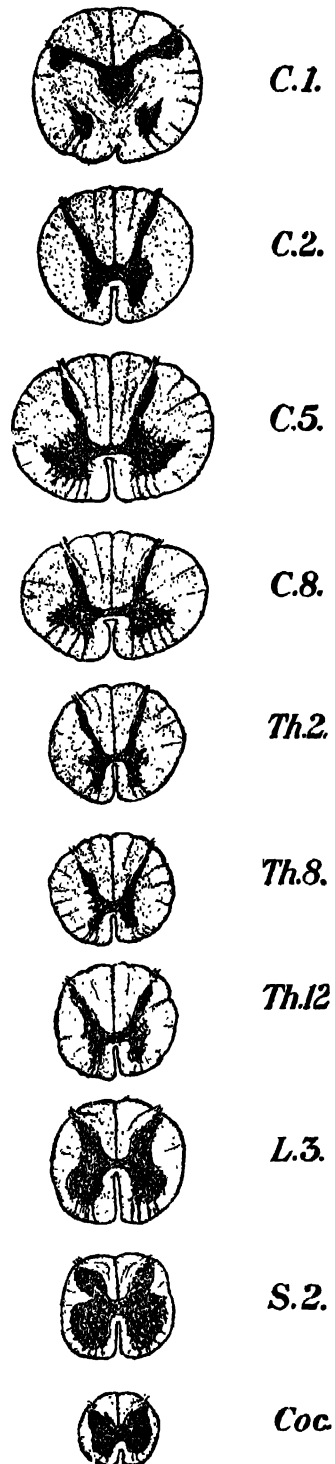

line by a transverse commissure of grey substance which is traversed by a small canal, the *central canal*, just visible to the naked eye. In a transverse section each half of the grey substance is shaped like a comma or crescent with its concavity directed laterally; and these, together with the intervening grey commissure, present the appearance of the letter H. An imaginary coronal plane through the central canal serves to divide each crescent into an anterior and a posterior column.

The **anterior column** (anterior cornu) is directed forwards; it is broad, and round or quadrangular in shape. Its posterior part is termed the *base*, and its anterior part the *head*, but these are not separated from each other by any well-defined constriction. Between the head of the anterior column and the surface of the medulla spinalis is a layer of white substance which is traversed by the bundles of the anterior nerve-roots. In the thoracic region, the posterior part of the anterior column projects lateralwards as a triangular field, named the **lateral column** (lateral cornu).

The **posterior column** (posterior cornu) is long and slender, and is directed backwards and lateralwards; it reaches almost as far as the posterolateral sulcus, from which it is separated by a thin layer of white substance, the *tract of Lissauer*. It consists of a *base*, directly continuous with the base of the anterior horn, and a *neck* or slightly constricted portion, which is succeeded by an oval or fusiform area, termed the *head*, of which the *apex* approaches the posterolateral sulcus. The apex is capped by a mass of translucent, gelatinous neuroglia, termed the *substantia gelatinosa* of *Rolando*, which contains both neuroglia-cells and small nerve-cells and is V-shaped or crescentic on transverse section. Between the anterior and posterior columns the grey substance extends as a series of processes into the lateral funiculus, and forms a network called the *formatio reticularis*.

The quantity of grey substance and the form it presents on transverse section vary at different levels. In the thoracic region the grey substance is small in amount, not only absolutely but relatively to the surrounding white substance. In the cervical and lumbar enlargements it is greatly increased; in the latter, and especially in the *conus medullaris*, its proportion to the white substance is greatest (fig. 719). In the cervical region the posterior column of grey substance is comparatively narrow, while its anterior is broad and expanded; in the thoracic region, both columns are narrow, and the lateral column is evident; in the lumbar enlargement the anterior and posterior columns are both expanded; while in the *conus medullaris* the grey substance assumes the form of two oval masses, one in either half of the cord, connected together by a broad grey commissure.

FIG. 719.—Transverse sections of the medulla spinalis at different levels.

The central canal traverses the entire length of the medulla spinalis. The grey substance in front of the canal is named the *anterior grey commissure*; that behind it, the *posterior grey commissure*. The anterior grey commissure is thin, and in contact anteriorly with the anterior white commissure: it contains a pair of longitudinal veins, one on either side of the middle line. The posterior grey commissure reaches from the central canal to the posterior median septum; is thinnest in the thoracic region, and thickest in the conus medullaris. The central canal is continued upwards through the lower part of the medulla oblongata and opens into the fourth ventricle of the brain; below it reaches for a short distance (5-6 cm.) into the filum terminale. In the lower part of the conus medullaris it exhibits a fusiform dilatation, the *terminal ventricle*; this has a vertical measurement of from 8 to 10 mm., is triangular on cross section with its base directed forwards, and tends to undergo obliteration after the age of forty years.

FIG. 720.—Section of the central canal of the medulla spinalis, showing the ependymal and neuroglial cells. (Lenhossék.)

Throughout the cervical and thoracic regions the central canal is situated in the anterior third of the medulla spinalis: in the lumbar enlargement it is near the middle, and in the conus medullaris it approaches the posterior surface. It is filled with cerebrospinal fluid, and lined by ciliated, columnar epithelium, which is encircled by a band of gelatinous substance, the *substantia gelatinosa centralis*. This gelatinous substance consists mainly of neuroglia, but contains a few nerve-cells and nerve-fibres; it is traversed by processes from the deep ends of the cells which line the central canal (fig. 720).

Structure of the grey substance.—The grey substance consists of nerve-cells, nerve-fibres and neuroglia. Throughout the greater part of it the neuroglia has the appearance of a sponge-like network, but around the central canal and on the apices of the posterior columns it consists of the gelatinous substance already referred to. The nerve-cells are multipolar, and vary greatly in size and shape. They consist of: (1) Motor cells of large size, which are situated in the anterior column, and are especially numerous in the cervical and lumbar enlargements; the axons of most of these cells pass out to form the anterior nerve-roots, but before leaving the white substance they frequently give off collaterals, which re-enter and ramify in the grey substance.* (2) Cells of small or medium size, whose axons pass into the white matter, where some pursue an ascending, and others a descending course, but most of them divide in a T-shaped manner into descending and ascending processes. They give off collaterals which enter and ramify in the grey substance, and the terminations of the axons behave in a similar manner. The lengths of these axons vary greatly: some are short and pass only between adjoining spinal segments,

* Lenhossék and Cajal found that in the embryo of the chick the axons of a few of these nerve-cells passed backwards through the posterior column, and emerged as the *motor fibres* of the *posterior nerve-roots*. These fibres are said to control the peristaltic movements of the intestine. Their presence in man has not yet been determined.

while others are longer and connect more distant segments. These cells and their processes constitute a series of *association* or *intersegmental neurons* (fig. 721), which link together the different parts of the medulla spinalis. The axons of most of these cells are confined to that side of the medulla spinalis in which the nerve-cells are situated, but some cross to the opposite side through the anterior commissure, and are termed *crossed commissural fibres*. Some of the latter end directly in the grey substance, while others enter the white substance, and ascend or descend in it for varying distances, before finally terminating in the grey substance. (3) Cells of type II. of Golgi, limited to the posterior column, are found in the substantia gelatinosa of Rolando; their axons are short and confined to the grey substance, in which they break up into numerous fine filaments. Most of the nerve-cells are arranged in longitudinal columns, and appear as groups on transverse section (figs. 722, 723).

Nerve-cells in the anterior column.—The nerve-cells in the anterior column are arranged in columns of varying length. The longest occupies the medial part of the anterior column and is named the *anteromedial* column: it is absent only in the fifth lumbar, the first sacral and the upper part of the second sacral segments (Bruce*). Behind it, is a *posteromedial* column of small cells, which extends from the second thoracic to the first lumbar segment and is also present in the first, sixth, and seventh cervical segments.

In the cervical and lumbar enlargements, where the anterior column is expanded in a lateral direction, the following additional columns are present, viz.—(a) *anterolateral*, in the fourth, fifth, and sixth cervical, second thoracic, lower four lumbar and upper two sacral segments; (b) *posterolateral*, in the lower five cervical, lower four lumbar, and upper three sacral segments; (c) *post-posterolateral*, in the last cervical, first thoracic, and upper three sacral segments; and (d) *central*, in the lower four lumbar and upper two sacral segments. Throughout the base of the anterior column are solitary cells, the axons of some of which form crossed commissural fibres, while others constitute the motor fibres of the posterior nerve-root (p. 750, footnote).

Nerve-cells in the lateral column.—These form a column which is best marked in the thoracic region; it extends from the middle of the eighth cervical segment to the lower part of the second lumbar or upper part of the third lumbar segment,† but can be traced throughout the entire length of the medulla spinalis in the form of groups of small cells situated in the anterior part of the *formatio reticularis*. The cells of this column are fusiform or star-shaped, and of a medium size: the axons of many of them pass into the anterior nerve-roots, and are conveyed to the sympathetic trunks through the white rami communicantes; while the axons of others pass into the anterior and lateral* funiculi, where they become longitudinal.

Nerve-cells in the posterior column.—1. The *dorsal nucleus* (column of Clarke) occupies the medial part of the base of the posterior column, and appears on transverse section as a well-defined oval area. It begins below at

FIG. 721.—Cells of medulla spinalis. (Poirier.)

† Bruce and Pirie, *British Medical Journal*, Nov. 17, 1906.

the level of the second or third lumbar nerve, and reaches its maximum size opposite the twelfth thoracic nerve. It diminishes in size above the level of the ninth thoracic nerve, and ends opposite the last cervical or first thoracic nerve. It is represented, however, in the other regions by scattered cells, which are aggregated to form a *cervical nucleus* opposite the third cervical nerve, and a *sacral nucleus* in the middle and lower part of the sacral region. Its cells are of medium size, and oval or pyriform in shape; many of their axons pass into the peripheral part of the lateral funiculus of the same side, and there ascend, under the name of the *direct cerebellar tract*; others cross to the opposite side and ascend as the *superficial anterolateral fasciculus*.

Nerve-cell of anterior column, the axon of which is passing into the posterior nerve-root. 7. Cells of substantia gelatinosa centralis. 8. Solitary cell. 9. Cells of Golgi. 10. Cells of origin of the superficial anterolateral fasciculus. 11. Anterior root. 12. Posterior root. 13. Spinal ganglion.

2. *Nerve-cells in the substantia gelatinosa of Rolando.*—These are arranged in three zones: a posterior or marginal, of large triangular or fusiform cells; an intermediate, of small fusiform cells; and an anterior, of star-shaped cells. The axons of these cells pass into the lateral and posterior funiculi, and there assume a vertical course. In the anterior zone some Golgi cells are found, the short axons of which ramify in the grey substance.

3. *Solitary cells of varying form and size* are scattered throughout the posterior column. Some of these are grouped to form the *posterior basal column* in the base of the posterior column, lateral to the dorsal nucleus. The posterior basal column is well-marked in the gorilla (Waldeyer), but ill-defined in man. The axons of its cells pass partly to the posterior and lateral funiculi of the same side, and partly through the anterior white commissure to the lateral funiculus of the opposite side. Before leaving the grey substance, a considerable number run longitudinally for a varying distance in the head of the posterior column, forming what is termed the *longitudinal fasciculus* of the posterior column.

A few star-shaped or fusiform nerve-cells of varying size are found in the substantia gelatinosa centralis. Their axons pass into the lateral funiculus of the same, or opposite, side.

The nerve-fibres in the grey substance form a dense interlacement among the nerve-cells. This interlacement is formed partly of axons which pass from the cells in the grey substance to enter the white funiculi or nerve-roots; partly of the axons of Golgi's cells which ramify only in the grey substance; and partly of collaterals from the nerve fibres in the white funiculi, which, as already stated, enter the grey substance and ramify within it.

White substance.—The white substance of the medulla spinalis consists of medullated nerve-fibres imbedded in a sponge-like network of neuroglia, and arranged in three funiculi: anterior, lateral, and posterior. The anterior funiculus lies between the anterior median fissure and the most lateral of the anterior nerve-roots; the lateral funiculus between these nerve-roots and the posterolateral sulcus; and the posterior funiculus between the posterolateral sulcus and the posterior median septum (fig. 724). The fibres vary in thickness; the thinnest are found in the fasciculus gracilis, the tract of Lissauer, and the central part of the lateral funiculus; the thickest are situated in the anterior funiculus, and in the peripheral part of the lateral funiculus. Some of the nerve-fibres assume a more or less transverse direction, as for example those which cross the middle line in the anterior white commissure, but the majority pursue a longitudinal course and are divisible into (1) those connecting the medulla spinalis with the brain, and conveying impulses to or from the latter, and (2) those which are confined to the medulla spinalis and link together its different segments (i.e. intersegmental or association fibres).

FIG. 723.—Transverse sections of the medulla spinalis at different levels to show the arrangement of the principal cell-columns.

Nerve-fasciculi.—The longitudinal fibres are grouped into more or less definite bundles or fasciculi. These are not recognisable from each other in the natural state, and their existence has been determined by the following methods: (1) A. Waller discovered that if a bundle of nerve-fibres be cut, the portions of the fibres which are separated from their cells rapidly degenerate and become atrophied, while the cells and the parts of the fibres connected with them undergo little alteration.* This is known as *Wallerian degeneration*. Similarly, if a group of nerve-cells be destroyed, the fibres arising from them undergo degeneration. Thus, if the motor cells of the cerebral cortex be destroyed, or if the fibres arising from these cells be severed, a *descending* degeneration from the seat of injury takes place in the fibres. In the same

FIG. 724.—Diagram of the principal fasciculi of white substance in the medulla spinalis.

manner, if a spinal ganglion be destroyed, or the fibres which pass from it into the medulla spinalis be cut, an *ascending* degeneration occurs in these fibres above the lesion. (2) By tracing the development of the nervous system, it has been observed that at first the nerve-fibres are naked axis-cylinders, and that all do not acquire their medullary sheaths at the same time; hence the fibres can be grouped according to the dates at which they receive their medullary sheaths. (3) Staining nervous tissues by Golgi's method which allows the course and mode of termination of the axis-cylinder processes to be followed.

Fasciculi in the anterior funiculus.—The principal fasciculus is the *anterior cerebrospinal* (direct pyramidal tract), which is usually small, but varies in size inversely with the lateral cerebrospinal fasciculus. It lies close to the anterior median fissure, and is present only in the upper part of the medulla spinalis; gradually diminishing in size as it descends, it ends about

* Somewhat later a change, termed *chromatolysis*, takes place in the nerve-cells, and consists of a breaking down and ultimate disappearance of the Nissl bodies. The cell-body is swollen, the nucleus is displaced towards the periphery of the cell, and the part of the axon still attached to the altered cell is diminished in size and somewhat atrophied. Under favourable conditions the cell may reassume its normal appearance, and its axon may grow again.

the middle of the thoracic region. It consists of descending fibres which arise from cells in the motor area of the cerebral hemisphere of the same side, and which, as they run downwards in the medulla spinalis, cross in succession through the anterior white commissure to the opposite side, where they end by arborising around the motor cells in the anterior column.

In addition to the anterior cerebrospinal fasciculus there are strands of fibres in the anterior funiculus connecting certain ganglia in the brain with the grey substance of the medulla spinalis. One of these is the *vestibulospinal*, situated chiefly in the marginal part of the funiculus and mainly derived from the cells of Deiters' nucleus, one of the terminal nuclei of the vestibular nerve. Some fibres pass downwards from the corpora quadrigemina (*tectospinal*) and others are continuous with the medial longitudinal fasciculus.

The remaining fibres of the anterior funiculus constitute what is termed the *anterior proper fasciculus* (anterior basis bundle). It consists mainly of: (1) longitudinal intersegmental fibres which arise from cells in the grey substance, more especially from those of the medial group of the anterior column, and, after a longer or shorter course, re-enter the grey substance. Some of the fibres of this fasciculus pass upwards into the medial (posterior) longitudinal fasciculus (p. 790); (2) fibres arising from cells of the cerebellum and extending down the medulla spinalis to end around the cells of the anterior column—these fibres constitute an irregular tract, *cerebellospinal tract of Loewenthal*, disposed in the peripheral portions of the anterior and lateral proper fasciculi.

Fasciculi in the lateral funiculus.—1. **Descending fasciculi.**—(a) The *lateral cerebrospinal fasciculus* (crossed pyramidal tract) extends throughout the entire length of the medulla spinalis, and on transverse section appears as an oval area in front of the posterior column and medial to the direct cerebellar fasciculus. Its fibres arise from cells in the motor area of the cerebral hemisphere of the opposite side. They pass downwards in company with those of the anterior cerebrospinal fasciculus through the same side of the brain as that from which they originate, but they cross to the opposite side in the medulla oblongata and descend in the lateral funiculus of the medulla spinalis; they end by arborising around the motor cells in the anterior column.*

The anterior and lateral cerebrospinal fasciculi constitute the motor fasciculi of the medulla spinalis and have their origins in the motor cells of the cerebral cortex. They descend through the internal capsule of the cerebrum, traverse the cerebral peduncles and pons and enter the pyramid of the medulla oblongata. In the lower part of the latter about two-thirds of them cross the middle line and run downwards in the lateral funiculus as the lateral cerebrospinal fasciculus, while the remaining fibres do not cross, but are continued into the same side of the medulla spinalis, where they form the anterior cerebrospinal fasciculus. The fibres of the latter, however, cross the middle line in the anterior white commissure, and thus, generally speaking, all the motor fibres from one side of the brain ultimately reach the opposite side of the medulla spinalis. The proportion of fibres which cross in the medulla oblongata is not a constant one, and thus the anterior and lateral cerebrospinal fasciculi vary inversely in size. Sometimes the former is absent, and in such cases it may be presumed that the decussation of the motor fibres in the medulla oblongata has been complete. The fibres of these two fasciculi do not acquire their medullary sheaths until after birth. There is experimental and clinical evidence to show that the lateral cerebrospinal fasciculus contains a few fibres derived from the cerebral hemisphere of the same side (*uncrossed lateral cerebrospinal fibres*).

(b) The *rubrospinal fasciculus* (Monakow) lies on the ventral aspect of the lateral cerebrospinal fasciculus and on transverse section appears as a somewhat

* Schäfer (*Proc. Physiological Soc.* 1899) says it is probable that the fibres of the anterior and lateral cerebrospinal fasciculi are not related in this direct manner with the cells of the anterior column, but terminate by arborising round the cells at the base of the posterior column and the cells of Clarke's column, which in turn link them to the motor cells in the anterior column, usually of several segments of the cord. In consequence of these interposed neurons the fibres of the cerebrospinal fasciculi correspond, not to individual muscles, but to associated groups of muscles.

triangular area. Its fibres descend from the mid-brain, where they have their origin in the cells of the red nucleus of the tegmentum of the opposite side.

(c) The *tectospinal fasciculus* originates in the superior colliculus (upper quadrigeminal body) of the opposite side, and its fibres are partly intermingled with those of the rubrospinal fasciculus, and are partly contained in the anterior funiculus.

(d) The *olivospinal fasciculus* (Helweg) arises in the vicinity of the inferior olivary nucleus in the medulla oblongata and is seen only in the cervical region of the medulla spinalis, where it forms a small triangular area at the periphery, close to the most lateral of the anterior nerve-roots. Its exact origin and its mode of ending have not yet been definitely made out.

2. **Ascending fasciculi.**—(a) The *direct cerebellar tract of Flechsig* is situated at the periphery of the posterior portion of the lateral funiculus, and on transverse section appears as a flattened band reaching as far forwards as a line drawn transversely through the central canal of the medulla spinalis. Medially it is in contact with the lateral cerebrospinal fasciculus, behind, with the fasciculus of Lissauer. It begins about the level of the second or third lumbar nerve, increases in size as it ascends, and finally passes to the cerebellum through the restiform body. Its fibres are generally regarded as being the axons of the cells of the dorsal nucleus (Clarke's column); they receive their medullary sheaths about the sixth or seventh month of fetal life.

(b) The *superficial anterolateral fasciculus* (tract of Gowers) skirts the periphery of the lateral funiculus in front of the direct cerebellar fasciculus. In transverse section it is shaped somewhat like a comma, the expanded end lying in front of the lateral cerebrospinal fasciculus while the tail reaches forwards into the anterior funiculus. Its fibres come from the cells of the grey substance of the opposite side of the medulla spinalis and are derived from the cells of the dorsal nucleus and from other cells of the posterior column. The superficial anterolateral fasciculus begins about the level of the third pair of lumbar nerves, and, increasing in size as it ascends, can be followed into the medulla oblongata and pons. It consists of three fasciculi: (1) the *anterior spinocerebellar*, the largest of the three, passes to the cerebellum by way of the brachia conjunctiva; (2) the *spinothalamic* ends in the thalamus, and is sometimes termed the *secondary sensory fasciculus*; and (3) the *spinotectal* passes to the corpora quadrigemina.

(c) The *fasciculus of Lissauer* is a small strand situated at the tip of the posterior column close to the entrance of the posterior nerve-roots. It consists of fine fibres which do not receive their medullary sheaths until towards the close of foetal life; some of its fibres are said to remain non-medullated throughout life. It is usually regarded as being formed by some of the lateral fibres of the posterior nerve-roots, which ascend for a short distance in the tract and then enter the posterior column, but its fibres are myelinated later than those of the posterior nerve-roots, and do not undergo degeneration in locomotor ataxia; they are probably intersegmental in character.

(d) The *lateral proper fasciculus* (lateral basis bundle) constitutes the remainder of the lateral column, and is continuous in front with the anterior proper fasciculus. It consists chiefly of intersegmental fibres which arise from cells in the grey substance, and, after a longer or shorter course, re-enter the grey substance and ramify in it. Some of its fibres are, however, continued upwards into the brain under the name of the medial longitudinal fasciculus.

Fasciculi in the posterior funiculus.—This funiculus comprises two main fasciculi, viz. the fasciculus gracilis and the fasciculus cuneatus. These are separated from each other in the cervical and upper thoracic regions by the postero-intermediate septum, and consist mainly of ascending fibres derived from the posterior nerve-roots.

The *fasciculus gracilis* (tract of Goll) is wedge-shaped on transverse section, and lies next the posterior median septum, its base being at the surface of the medulla spinalis, and its apex directed towards the posterior grey commissure. It increases in size from below upwards (fig. 725), and consists of long thin fibres which are derived from the posterior nerve-roots, and ascend as far as the medulla oblongata, where they end in the nucleus gracilis.

The *fasciculus cuneatus* (tract of Burdach) is triangular on transverse section, and lies between the fasciculus gracilis and the posterior grey column, its base

corresponding with the surface of the medulla spinalis. Its fibres, larger than those of the fasciculus gracilis, are mostly derived from the same source, viz. the posterior nerve-roots. Some of its fibres ascend for only a short distance, and, entering the grey substance, come into close relationship with the cells of the dorsal nucleus; others can be traced as far as the medulla oblongata, where they end in the nucleus gracilis and nucleus cuneatus.

FIG. 725.—Diagram showing the formation of the fasciculus gracilis. (Poirier.)

The medulla spinalis viewed from behind. To the left, the fasciculus gracilis is shaded. To the right, the drawing shows that the fasciculus gracilis is formed by the long ascending fibres of the posterior roots and that the sacral nerves lie next the median plane, the lumbar to their lateral side, and the thoracic still more laterally.

FIG. 726.—The descending fibres in the posterior funiculi, shown at different levels. (After Testut.)

A. In the conus medullaris. B. In the lumbar region. C. In the lower thoracic region. D. In the upper thoracic region.

Occupying the ventral part of the posterior funiculus is a strand of fibres termed the *cornucommissural fasciculus*. It is somewhat crescentic on transverse section, and is placed between the posterior grey commissure and the posterior column; it is best marked in the lumbar region, but can be traced into the thoracic and cervical regions. Its fibres, derived from the cells of the posterior column, divide into ascending and descending branches which re-enter and ramify in the grey substance. This fasciculus has been found to preserve its integrity in certain cases of locomotor ataxia.

Descending fibres in the posterior funiculus (fig. 726).—The posterior funiculus

contains some descending fibres which occupy different parts at different levels. In the cervical and upper thoracic regions, they appear as a *comma-shaped fasciculus* in the medial part of the fasciculus cuneatus, the blunt edge of the fasciculus being directed forwards; in the lower thoracic region they form a *dorsal peripheral band* on the posterior surface of the funiculus; in the lumbar region, they are situated by the side of the posterior median septum, and appear on section as a semi-elliptical bundle, which, together with the corresponding bundle of the opposite side, forms the *oval area of Flechsig*; while in the conus medullaris they assume the form of a *triangular strand* in the posteromedial part of the fasciculus gracilis. These descending fibres are mainly intersegmental in character and derived from cells in the posterior column, but some consist of the descending branches of the posterior nerve-roots. The comma-shaped fasciculus was supposed to belong to the second category,

FIG. 727.—A spinal nerve with its anterior and posterior roots. (Testut.)

1. A portion of the medulla spinalis viewed from the left side. 2. Anterior median fissure. 3. Anterior column. 4. Posterior column. 5. Lateral column. 6. Formatio reticularis. 7. Anterior root. 8. Posterior root, with 8', its ganglion. 9. Spinal nerve; 9', its posterior division.

but against this view is the fact that it does not undergo descending degeneration when the posterior nerve-roots are destroyed.

Roots of the spinal nerves.—

As already stated, each spinal nerve possesses two roots, an anterior and a posterior, which are attached to the surface of the medulla spinalis opposite the corresponding column of gray substance (fig. 727); their fibres acquire their medullary sheaths about the fifth month of foetal life.

The *anterior nerve-root* consists of efferent fibres, which are the axons of the nerve-cells in the ventral part of the anterior column. A short distance from their origins, these axons are invested by medullary sheaths and, passing forwards, emerge in two or three irregular rows over an area which measures about 3 mm. in width.

The *posterior root* comprises six or eight fasciculi, attached in linear series along the posterolateral sulcus.

It consists of afferent fibres which

arise from the nerve-cells in a spinal ganglion. Each ganglion-cell gives off a single fibre which divides in a T-shaped manner into two processes, medial and lateral. The medial processes of the ganglion-cells pass into the medulla spinalis as the posterior roots of the spinal nerves, while the lateral are directed towards the periphery.

The posterior nerve-root enters the medulla spinalis in three chief bundles, medial, intermediate, and lateral. The *medial* strand passes directly into the fasciculus cuneatus; it consists of coarse fibres, which acquire their medullary sheaths about the fifth month of intra-uterine life; the *intermediate* strand consists of coarse fibres, which enter the gelatinous substance of Rolando; the *lateral* strand is composed of fine fibres, which are said to assume a longitudinal direction in the tract of Lissauer.

After entering the medulla spinalis, all the fibres of the posterior nerve-roots divide into ascending and descending branches, and these in their turn give off collaterals which enter the grey substance (fig. 728). The descending branches are short, and soon enter the grey substance. The ascending branches are grouped into long, short, and intermediate fibres: the long fibres ascend in the fasciculus cuneatus and fasciculus gracilis as far as the medulla oblongata, where they end by arborising around the cells of the cuneate and gracile nuclei; the short fibres run upwards for a distance of only 5 or 6 mm., and enter the grey substance; while the intermediate fibres, after a somewhat longer course, have a similar destination. All fibres entering the grey substance end by arborising around its nerve cells; in the thoracic region those of intermediate

length are especially associated with the cells of the dorsal nucleus. The collaterals which spring from the ascending and descending branches of the fibres of the posterior nerve-roots end by arborising around the cells in the anterior and posterior grey columns; in the thoracic region many of these collaterals arborise around the cells of the dorsal nucleus and the cells of the lateral grey column.

The long ascending fibres of the posterior nerve-roots pursue an oblique course upwards, being situated at first in the lateral part of the fasciculus cuneatus: higher up, they occupy the middle of this fasciculus, having been displaced by the accession of other entering fibres; while still higher, they ascend in the fasciculus gracilis. The upper cervical fibres do not reach this fasciculus, but are entirely confined to the fasciculus cuneatus. The localisation of these fibres is very precise: the sacral nerves lie in the medial part of the fasciculus gracilis and near its periphery, the lumbar nerves lateral to them, the thoracic nerves still more laterally; while the cervical nerves are confined to the fasciculus cuneatus (fig. 725).

The development of the medulla spinalis is described in the section on Embryology (pp. 86 to 90).

FIG. 728.—Posterior nerve-roots entering the medulla spinalis and dividing into ascending and descending branches. (Van Gehuchten.)

Applied Anatomy.—Several cases have been recorded* in which a local doubling of the medulla spinalis has taken place. The condition is probably due to some interference with the development of the neural tube in the embryo; in a few it was associated with spina bifida, while in one recent case† the two parts were separated by a dermoid tumour. Other congenital abnormalities of the medulla spinalis occur in connexion with spina bifida (see p. 181), and *syringomyelia*. In this latter chronic condition an abnormal proliferation of the neuroglia takes place, generally near the central canal and in the cervical enlargement, and later this mass becomes absorbed, leaving an irregular cavity in its place. This gives rise to a number of interesting signs and symptoms, such as analgesia (or insensitiveness to pain), inability to distinguish between cold and heat, progressive atrophy in the muscles of the hands and arms, trophic changes in the bones and joints, and painless whitlows. Severe injuries to the medulla spinalis may occur in fractures or fracture-dislocations of the vertebral column anywhere above the second lumbar vertebra. If the medulla spinalis is completely crushed or torn across, total paralysis and anaesthesia of all parts of the body drawing their nerve supply from below the injured spot will follow, with loss of control over the actions of the bladder and rectum. The higher up such a lesion occurs, the worse the prognosis. Thus, in fracture of the atlas or epistropheus, the vital centres in the medulla oblongata are injured, and death occurs at once. If the origin of the phrenic nerve—mainly the fourth cervical—just escape in a case where the neck is broken, respiration will have to be carried on by the Diaphragm alone, and death is likely to ensue before long from pulmonary complications. When the back is broken in the lower thoracic region, life is not immediately threatened; but unless the patient is carefully nursed, death may follow at any time from the development of bed sores in the anaesthetic area, or from septic infection spreading up the ureters into the

* An analysis of these cases is given in the *Review of Neurology and Psychiatry*, Jan. 1916.

† Harriehausen, *D. Zeitschrift. f. Nervenheilk.* Bd. 36, Hft. 3 und 4, S. 268.

kidneys and secondary to the cystitis that is so prone to occur in patients who have no control over the bladder. *Inflammation of the medulla spinalis, or spinal myelitis*, sometimes follows influenza or one of the acute specific fevers. A transverse patch of such myelitis extending completely across the medulla spinalis produces more or less complete interruption of the passage of nervous impulses through it. Hence it will occasion more or less complete paralysis and anaesthesia of the parts of the body obtaining their nerve-supply from below it, and, in addition, a zone of cutaneous hyperaesthesia at its level, in consequence of the irritation of the sensory fibres entering the inflamed region of the medulla spinalis. The disease mainly attacking children, and known as *infantile spinal paralysis*, or *acute anterior poliomyelitis*, is a bacterial infection of the pia mater that spreads into the medulla spinalis along the blood-vessels, and destroys groups of the motor neurons aggregated in the anterior column. Destruction of the cells causes rapid and permanent paralysis of the muscles innervated, and groups of muscles in one or more of the limbs are commonly picked out for attack. The affected limbs are thus partially paralysed, and their subsequent growth and nutrition both suffer. Further, the muscles that normally antagonise the affected groups of muscles, finding their actions unopposed, tend to assume a state of spastic contraction. In consequence, much dwarfing and deformity follow later, and may demand for their relief such operations as tenotomy, the transplantation of tendons, or even amputation.

Inflammation of the ganglia on one or more of any of the posterior nerve-roots is the cause of *shingles** or herpes zoster, in which there is a painful eruption of groups of cutaneous vesicles corresponding to the distribution of the nerves derived from the affected ganglia. It is commonest along the course of the intercostal nerves; the eruption is often preceded and followed, as well as accompanied, by girdle pains, and in old people these may be prolonged and serious in character. Herpes is the analogue on the sensory side to anterior poliomyelitis on the motor side of the nervous system.

THE ENCEPHALON OR BRAIN

GENERAL CONSIDERATIONS AND DIVISIONS

The encephalon, or brain, is the upper, expanded part of the central nervous system, and is contained within the cranium. In the early embryo it consists

FIG. 729.—Scheme showing the connexions of the several parts of the brain. (After Schwalbe.)

of three hollow vesicles, termed the *rhombencephalon* or *hind-brain*, the *mesencephalon* or *mid-brain*, and the *prosencephalon* or *fore-brain*; and the parts derived from each of these can be recognised in the adult (fig. 729). The wall of the rhombencephalon is modified to form the medulla oblongata, pons, and cerebellum, while its cavity is expanded to form the fourth ventricle. The mesencephalon forms only a small part of the adult brain; its cavity becomes the cerebral aqueduct (aqueduct of Sylvius), which serves as a tubular communication between the third and fourth ventricles; while its walls

are thickened to form the corpora quadrigemina and the cerebral peduncles. The prosencephalon undergoes great modification: its anterior part or telencephalon expands laterally as two hollow vesicles the cavities of which become the lateral ventricles, while the surrounding walls form the cerebral hemispheres and their commissures; the cavity of the posterior part or diencephalon forms the greater part of the third ventricle, and from its walls are developed most of the structures which bound that cavity. Further details regarding these

* Lat. *cingulum*, a belt.

important changes are given in the chapter on Embryology, and the student is recommended to read pages 90 to 100 before commencing the study of the brain.

THE RHOMBENCEPHALON OR HIND-BRAIN

The **rhombencephalon** or **hind-brain** occupies the posterior fossa of the cranial cavity and lies below a fold of dura mater, named the **tentorium cerebelli**. It consists of (a) the *myelencephalon*, comprising the medulla oblongata and the lower part of the fourth ventricle; (b) the *metencephalon*, consisting of the pons, cerebellum, and the intermediate part of the fourth ventricle; and (c) the *isthmus rhombencephali*, a constricted portion immediately adjoining the mesencephalon and including the brachia conjunctiva of the cerebellum, the anterior medullary velum, and the upper part of the fourth ventricle.

THE MEDULLA OBLONGATA

The **medulla oblongata**, the lowest division of the brain, is extremely complex in structure, since it gives attachment to many of the cerebral nerves, and forms the connecting link between the medulla spinalis below and the cerebrum and cerebellum above.

It extends from the lower margin of the pons to a plane passing transversely below the pyramidal decussation and above the first pair of cervical nerves; this plane corresponds with the upper border of the atlas behind, and the middle of the dens of the epistropheus in front; at this level the medulla oblongata is continuous with the medulla spinalis. The anterior surface of the medulla oblongata is separated from the basilar part of the occipital bone and the upper part of the dens of the epistropheus by the membranes of the brain and the occipito-axial ligaments. Its posterior surface is received into the fossa between the hemispheres of the cerebellum, and the upper portion of it forms the lower part of the floor of the fourth ventricle. The vertebral arteries pass upwards and forwards in relation to its lateral surfaces; they then curve forwards to its anterior surface and unite at the lower border of the pons to form the basilar artery.

The medulla oblongata is pyramidal in shape (fig. 730), its broad extremity being directed upwards towards the pons, while its narrow lower end is continuous with the medulla spinalis. It measures about 3 cm. in length, about 2 cm. transversely at its widest part, and about 1.25 cm. anteroposteriorly. The central canal of the medulla spinalis is prolonged into its lower half, and then opens into the cavity of the fourth ventricle; the medulla oblongata may therefore be divided into a lower *closed part* containing the central canal, and an upper *open part* corresponding with the lower portion of the fourth ventricle. Its anterior and posterior surfaces are marked by median fissures.

The **anterior median fissure** contains a fold of pia mater, and extends along the entire length of the medulla oblongata; below, it is continuous with the anterior median fissure of the medulla spinalis; above, it ends at the lower border of the pons in a small triangular expansion, termed the *foramen cæcum*.

FIG. 730.—The medulla oblongata and pons. Anterior surface.

Its lower part is interrupted by bundles of fibres which cross obliquely from one side to the other, and constitute the *pyramidal decussation*. Some fibres, termed the *external arcuate fibres*, emerge from the fissure above this decussation and curve lateralwards and upwards over the surface of the medulla oblongata.

The *posterior median fissure* is a narrow groove which exists only in the closed part of the medulla oblongata; it is continuous below with the *posterior median sulcus* of the medulla spinalis, becomes gradually shallower from below upwards, and finally ends about the middle of the medulla oblongata, where the central canal expands into the cavity of the fourth ventricle.

between it and the pons the fibres of the abducent nerve emerge; below, it tapers into the anterior funiculus of the medulla spinalis, with which, at first sight, it appears to be directly continuous.

The two pyramids contain the motor fibres which pass from the brain to the medulla spinalis. When traced downwards, two-thirds, or more, of these fibres leave the pyramids in successive bundles, and decussate in the anterior median fissure, forming what is termed the *pyramidal decussation*. Having crossed the middle line, they pass down in the posterior part of the lateral funiculus of the medulla spinalis as the lateral cerebrospinal fasciculus. The remaining fibres—i.e. those which occupy the lateral part of the pyramid—do not cross the middle line, but descend as the anterior cerebrospinal

These two fissures divide the closed part of the medulla oblongata into lateral halves, each presenting elongated eminences which, on surface view, are continuous with the funiculi of the medulla spinalis. In the open part the halves are separated by the anterior median fissure, and by a median *raphe* which extends from the bottom of the fissure to the median sulcus of the rhomboid fossa or floor of the fourth ventricle. Further, certain of the cerebral nerves pass through the substance of the medulla oblongata, and are attached to its surface in series with the roots of the spinal nerves; thus, the fibres of the hypoglossal nerve correspond in position with the anterior roots of the spinal nerves, and emerge in linear series from a furrow termed the *anterolateral sulcus*. Similarly, the accessory, vagus, and glossopharyngeal nerves correspond with the posterior roots of the spinal nerves, and are attached to the bottom of a sulcus named the *posterolateral sulcus*. Advantage is taken of this arrangement to subdivide each half of the medulla oblongata into three regions, anterior, middle, and posterior. Although these three regions appear to be directly continuous with the corresponding funiculi of the medulla spinalis, they do not necessarily contain the same nerve-fibres since some of the fasciculi of the medulla spinalis end in the medulla oblongata, while others alter their course in passing through it.

The anterior region of the medulla oblongata (fig. 730) is named the *pyramid*, and lies between the anterior median fissure and the anterolateral sulcus. Its upper end is slightly constricted, and

fasciculus (fig. 731) into the anterior funiculus of the same side of the medulla spinalis.

The greater part of the anterior proper fasciculus of the medulla spinalis is continued upwards through the medulla oblongata under the name of the *medial longitudinal fasciculus*.

The lateral region of the medulla oblongata (fig. 732) is limited in front by the anterolateral sulcus and the roots of the hypoglossal nerve, and behind by the posterolateral sulcus and the roots of the accessory, vagus, and glossopharyngeal nerves. Its upper part consists of a prominent oval mass which is named the olive, while its lower part is of the same width as the lateral funiculus of the medulla spinalis, and appears on the surface to be a direct continuation of it. As a matter of fact, only a portion of the lateral funiculus of the medulla spinalis is continued upwards into this region, for the lateral

FIG. 732.—The hind-brain and mid-brain; posterolateral view.

cerebrospinal fasciculus passes into the pyramid of the opposite side, and the direct cerebellar tract is carried into the restiform body in the posterior region. The remainder of the lateral funiculus, which consists chiefly of the lateral proper fasciculus and the superficial anterolateral fasciculus, can be traced into the lateral region. Most of these fibres dip beneath the olive and disappear from the surface; but a small strand remains superficial, and ascends between the olive and the posterolateral sulcus. In a depression at the upper end of this strand is the acoustic nerve.

The *olive* is situated lateral to the pyramid, from which it is separated by the anterolateral sulcus and the fibres of the hypoglossal nerve. Behind, it is separated from the posterolateral sulcus by the small superficial strand of the lateral funiculus already referred to. It is about 1.25 cm. long, and between its upper end and the pons there is a slight depression to which the roots of the facial nerve are attached. The external arcuate fibres wind backwards across the lower part of the pyramid and olive and enter the restiform body.

The posterior region of the medulla oblongata (fig. 733) lies behind the posterolateral sulcus and the roots of the accessory, vagus, and glossopharyngeal nerves, and, like the lateral region, is divisible into a lower and an upper portion.

The lower part is limited behind by the posterior median fissure, and consists of the *fasciculus gracilis* and the *fasciculus cuneatus*, the direct upward prolongations of the posterior funiculi of the medulla spinalis. The *fasciculus gracilis* is placed parallel to and along the side of the posterior median fissure, and is separated from the *fasciculus cuneatus* by the postero-intermediate sulcus and septum. The *fasciculus gracilis* and *fasciculus cuneatus* are at first vertical; but at the lower part of the rhomboid fossa they diverge from the middle line in a V-shaped manner, and each presents an elongated swelling.

FIG. 733.—The upper part of the medulla spinalis and the hind- and mid-brains; exposed from behind.

The swelling on the *fasciculus gracilis* is named the *clava*, and is produced by a subjacent nucleus of grey matter, the *nucleus gracilis*; that on the *fasciculus cuneatus* is termed the *cuneate tubercle*, and is caused by a grey nucleus, named the *nucleus cuneatus*. The fibres of these two fasciculi end by arborising around the cells in their respective nuclei. A third elevation, named the *tuberculum cinereum* (tubercle of Rolando), is present in the lower part of the posterior region of the medulla oblongata. It lies between the *fasciculus cuneatus* and the roots of the accessory nerve, and is narrow below but wider above; it ends superiorly at a distance of about 1.25 cm. below the pons. It is produced by a nucleus of grey substance which is continuous below with the *substantia gelatinosa* of Rolando, and in which the fibres of the *tractus spinalis*, or spinal root, of the trigeminal nerve ends; these fibres separate it from the surface of the medulla oblongata.

The *upper part* of the posterior region of the medulla oblongata is occupied by the *restiform body*, a thick rope-like strand situated between the lower part of the fourth ventricle and the roots of the glossopharyngeal and vagus nerves. The two restiform bodies connect the medulla spinalis and medulla oblongata with the cerebellum, and are sometimes named the *inferior peduncles of the cerebellum*. As they ascend, they diverge from one another, and assist in forming the lower parts of the lateral boundaries of the fourth ventricle: higher up, they are directed backwards, each passing to the corresponding cerebellar hemisphere. Near their entrance into the cerebellum they are crossed by several strands of fibres, which run to the median sulcus of the rhomboid fossa and are named the *striae medullares*. The restiform body appears to be the upward continuation of the fasciculus gracilis and fasciculus cuneatus, but the fibres of these fasciculi end in the nucleus gracilis and nucleus cuneatus: its constitution will be subsequently discussed.

Internal structure of the medulla oblongata.—Although the external form of the medulla oblongata bears a certain resemblance to that of the upper

part of the medulla spinalis, its internal structure differs widely from that of the latter, and this for the following principal reasons: (1) certain fasciculi of nerve-fibres which extend from the medulla spinalis to the brain, or vice versa, undergo a rearrangement in their passage through the medulla oblongata; (2) other fasciculi of the medulla spinalis end in the medulla oblongata; (3) new fasciculi originate in the grey substance of the medulla oblongata and pass to different parts of the brain; (4) the grey substance, which in the medulla spinalis forms a continuous H-shaped column, is greatly modified and subdivided in the medulla oblongata, where also new masses of grey substance are added: (5) on account of the opening out of the central canal of the medulla spinalis, certain parts of the grey substance, which in the medulla spinalis were more or less centrally situated, are displayed in the rhomboid fossa; (6) the medulla oblongata is intimately associated with many of the cerebral nerves, some arising from, and others ending in, nuclei within its substance.

The internal structure of the medulla oblongata is best studied in a series of transverse (figs. 738, 739) and longitudinal sections. A short description of the course taken by the principal fasciculi, and of the arrangement of the grey substance, will now be given.

The cerebrospinal fasciculi.—The downward course of these fasciculi from the pyramids of the medulla oblongata and their partial decussation have already been described (p. 755). In crossing to reach the lateral funiculus

of the opposite side, the fibres of the lateral cerebrospinal fasciculi run backwards through the anterior columns, and separate the head of each of these columns from its base (figs. 734, 735). The base retains its position in relation to the ventral aspect of the central canal, and, when the latter opens into the fourth ventricle, appears in the rhomboid fossa, or floor of the ventricle, close to the middle line, where it forms the nuclei of the hypoglossal and abducent nerves; while, above the level of the ventricle it exists as the nuclei of the trochlear and oculomotor nerves in relation to the floor of the cerebral aqueduct. The head of the column is pushed lateralwards and forms the *nucleus ambiguus* which gives origin from below upwards to the cerebral

part of the medulla oblongata, where they end respectively in the nucleus gracilis and nucleus cuneatus. These two nuclei are continuous with the central grey substance of the medulla spinalis, and may be regarded as dorsal projections of it, each being covered superficially by the fibres of the corresponding fasciculus. On transverse section (fig. 738), the nucleus gracilis appears as a single, more or less quadrangular mass, while the nucleus cuneatus consists of two parts: a larger, somewhat triangular, *medial nucleus*, composed of small or medium-sized cells, and a smaller *lateral nucleus* containing large cells.

The fibres of the fasciculus gracilis and fasciculus cuneatus end by arborising around the cells of these nuclei (fig. 736). From the cells of the nuclei new fibres arise; some of these are continued as the external arcuate fibres into the restiform body of the same side, and through it to the cerebellum, but most of them pass forwards as the *internal arcuate fibres* through the neck of the

part of the accessory nerve and the motor fibres of the vagus and glossopharyngeal nerves; higher up, the head of the column is represented by the motor nuclei of the facial and trigeminal nerves.

The *fasciculus gracilis* and *fasciculus cuneatus* constitute the posterior sensory fasciculi of the medulla spinalis; they are prolonged upwards into the lower

posterior column, thus cutting off its head from its base (fig. 737). Curving forwards, they decussate in the middle line with the corresponding fibres of the opposite side, and run upwards immediately behind the cerebrospinal fibres, as a flattened band, named the *lemniscus* or *fillet*. The decussation of those sensory fibres is situated above that of the motor fibres, and constitutes the *decussation of the lemniscus* or *sensory decussation*. The lemniscus is joined by the spinothalamic fasciculus (p. 756), the fibres of which are derived from the cells of the posterior grey column of the opposite side of the medulla spinalis.

The base of the posterior column at first lies on the dorsal aspect of the central canal, but when the latter opens into the fourth ventricle, it appears in the lateral part of the rhomboid fossa. It forms the terminal nuclei of the

FIG. 738.—Section of the medulla oblongata at about the middle of the olive. (Schwalbe.)

sensory fibres of the vagus and glossopharyngeal nerves, and is associated with the vestibular part of the acoustic nerve and the sensory root of the facial nerve. Still higher, it forms a mass of pigmented cells—the *locus ceruleus*—in which some of the sensory fibres of the trigeminal nerve appear to end. The head of the posterior column forms a long nucleus, in which the fibres of the spinal tract of the trigeminal nerve largely end.

The **direct cerebellar fasciculus** leaves the lateral region of the medulla oblongata; most of its fibres are carried backwards into the restiform body of the same side, and through it are conveyed to the cerebellum; but some run upwards with the fibres of the lemniscus, and, reaching the inferior colliculus, undergo decussation, and are carried to the cerebellum through the *brachium conjunctivum*.

The **proper fasciculi** (basis bundles) of the anterior and lateral funiculi largely consist of intersegmental fibres, which link together the different segments of the medulla spinalis; they assist in the production of the *formatio reticularis* of the medulla oblongata, and many of them are accumulated into a fasciculus which runs up close to the median raphe between the lemniscus

and the rhomboid fossa; this strand is named the *medial longitudinal fasciculus*, and will be again referred to.

Grey substance of the medulla oblongata (figs. 738, 739).—In addition to the gracile and cuneate nuclei, there are several other nuclei to be considered. Some of these are traceable from the grey substance of the medulla spinalis, while others are unrepresented in it.

1. The *hypoglossal nucleus* is derived from the base of the anterior column; in the lower, closed part of the medulla oblongata it is situated on the ventrolateral aspect of the central canal; but in the upper, open part it approaches the rhomboid fossa, where it lies close to the middle line, under an eminence named the *trigonum hypoglossi* (fig. 753). The nucleus measures about 2 cm. in length, and consists of large multipolar nerve-cells the axons of which constitute the

FIG. 739.—Transverse section of the medulla oblongata below the middle of the olive.

roots of the hypoglossal nerve. These nerve-roots pass forward between the anterior and lateral regions of the medulla oblongata, and emerge at the anterolateral sulcus.

2. The *motor nucleus* (figs. 740, 741), common to the *glossopharyngeal*, *vagus*, and cerebral part of the *accessory nerves*, is named the *nucleus ambiguus*. It represents the head of the anterior column, lies deeply in the formation *reticularis grisea*, and extends throughout nearly the whole length of the medulla oblongata.

3. The terminal nucleus of the sensory fibres of the *glossopharyngeal* and *vagus* represents the base of the posterior column (figs. 740, 742). It measures about 2 cm. in length, and in the lower, closed part of the medulla oblongata is situated behind the hypoglossal nucleus; whereas in the upper, open part it lies lateral to that nucleus, and corresponds to an area, named the *ala cinerea* or *trigonum vagi*, in the rhomboid fossa.

4. The *nuclei of the acoustic nerve* are described on p. 775.

5. The *olivary nuclei* (fig. 738) are three in number on either side of the middle line, viz. the *inferior olivary nucleus*, and the *medial and dorsal accessory olivary nuclei*; they consist of small, round, yellowish cells and numerous fine nerve-fibres. (a) The *inferior olivary nucleus* is the largest, and is situated within the olive. It consists of a grey folded lamina arranged

in the form of an incomplete capsule, opening medially by an aperture called the *hilum*; emerging from the hilum are numerous fibres which collectively constitute the *peduncle of the olive*. (b) The *medial accessory olivary nucleus* lies between the inferior olivary nucleus and the pyramid, and forms a curved lamina, the concavity of which is directed laterally. The fibres of the hypoglossal nerve, as they traverse the medulla, pass between the medial accessory and the inferior olivary nuclei. (c) The *dorsal accessory olivary nucleus* is the smallest, and appears on transverse section as a curved lamina behind the inferior olivary nucleus.

The inferior olivary nucleus is connected—(1) with that of the opposite side by fibres which cross through the raphe; (2) with the anterior column of the same side of the medulla spinalis by the *spino-olivary fasciculus*; (3) with the thalamus of the cerebrum by the *cerebro-olivary fasciculus* which passes through the pons and tegmentum; (4) with the opposite cerebellar hemisphere by the *cerebello-olivary fasciculus* (fig. 743), the fibres of which cross the raphe and turn backwards to enter the deep part of the restiform body. Removal of one cerebellar hemisphere is followed by atrophy of the opposite olivary nucleus.

6. The *nucleus arcuatus* is described below with the external arcuate fibres.

Restiform bodies.—The position of the restiform bodies has already been described (p. 765). Each comprises: (1) the direct cerebellar tract, which ascends from the lateral funiculus of the same side of the medulla spinalis; (2) the cerebello-olivary fasciculus described above; (3) descending cerebellar fibres, many of which are disseminated throughout the peripheral part of the anterior and lateral funiculi of the medulla spinalis, while others pass to the motor nuclei of the cerebral nerves; and (4) the external arcuate fibres.

The *external arcuate fibres* vary as to their prominence in different cases: in some they form an almost continuous layer covering the pyramid and olive while in others they are barely visible on the surface. They arise from the cells of the nucleus gracilis and nucleus cuneatus, pass forwards through the formatio reticularis, and decussate in the middle line. Most of them reach the surface by way of the anterior median fissure, and arch backwards over the pyramid. Reinforced by others which emerge between the pyramid and olive, they pass backwards over the olive and lateral region of the medulla

FIG. 740.—The nuclei of the cerebral nerves schematically represented; dorsal view. Motor nuclei, in red; sensory in blue. (The olfactory and optic centres are not represented.)

FIG. 742.—The primary terminal nuclei of the afferent (sensory) cerebral nerves schematically represented; lateral view. The olfactory and optic centres are omitted.

oblongata, and enter the restiform body. They thus connect the cerebellum with the nucleus gracilis and nucleus cuneatus of the opposite side. As the fibres arch across the pyramid, they enclose a small nucleus which lies in front of and medially to the pyramid. This is named the *nucleus arcuatus*, and is serially continuous above with the nuclei pontis: it contains small fusiform cells, around which some of the arcuate fibres end, and from which others arise.

A few fibres are said to arise from the nucleus gracilis and nucleus cuneatus and to pass to the restiform body of the same side.

Formatio reticularis (fig. 744).—This term is applied to the coarse reticulum which occupies the anterior and lateral regions of the medulla oblongata. It is situated behind the pyramid and olive, extending laterally as far as the restiform bodies, and dorsally to within a short distance of the rhomboid fossa. The reticulum is caused by the intersection of bundles of fibres running at right angles to each other, some being longitudinal, others more or less transverse in direction. In the formatio reticularis of the anterior region, there is an almost entire absence of nerve-cells, and hence this part is known as the *substantia reticularis alba*; whereas in the lateral region nerve-cells are numerous, and as a consequence the formatio presents a grey appearance, and is termed the *substantia reticularis grisea*.

In the substance of the formatio reticularis are two small nuclei of grey matter: one, the *nucleus of Roller*, near the ventral surface of the hypoglossal nucleus; the other, the *nucleus lateralis*, between the olive and the spinal tract of the trigeminal nerve.

In the *substantia reticularis alba* the longitudinal fibres form two well-defined fasciculi, viz.: (1) the *lemniscus*, which lies close to the raphe, immediately behind the fibres of the pyramid; and (2) the *medial longitudinal fasciculus*, which is continued upwards from the anterior and lateral proper fasciculi of the medulla spinalis, and in the upper part of the medulla oblongata lies between the lemniscus and the grey substance of the rhomboid fossa. The longitudinal fibres in the *substantia reticularis grisea* are derived from fasciculi of the lateral funiculus of the medulla spinalis with the exception of the lateral

cerebrospinal fasciculus, which has passed over to the anterior region of the opposite side, and the direct cerebellar fasciculus which has entered the restiform body. They form indeterminate fibres, with the exception of a bundle named the *fasciculus solitarius*, which consists of descending fibres of the vagus and glossopharyngeal nerves. The transverse fibres of the formatio reticularis are the arcuate fibres already described (pp. 767, 769).

Applied Anatomy.—In *bulbar paralysis*, i.e. paralysis of the medulla oblongata, which is really a special form of a progressive degeneration affecting the whole efferent or motor tract, the disease begins with impairment of the movements of the lips, tongue, pharynx, and larynx, due to degeneration of the motor cells in the nuclei of the medulla oblongata. Speech and swallowing become difficult, and the saliva dribbles from the open mouth. Other groups of muscles soon become involved, and death often occurs from 'aspiration pneumonia,' set up by food that has accidentally passed down the trachea.

THE PONS

The **pons** (pons Varolii) or fore part of the rhombencephalon is situated in front of the cerebellum. From its superior surface the cerebral peduncles emerge, one on either side of the middle line. Curving round each peduncle, close to the upper surface of the pons, a thin white band, the *tænia pontis*, is frequently seen; it enters the cerebellum between the brachium pontis and brachium conjunctivum. Behind and below, the pons is continuous with the medulla oblongata, but is separated from it in front and laterally by a transverse furrow in which the abducent, facial, and acoustic nerves appear.

Its *ventral* or *anterior surface* is prominent, markedly convex from side to side, less so from above downwards. It consists of transverse fibres arched like a bridge across the middle line, and gathered on either side into a compact mass which forms the brachium pontis. It rests upon the clivus of the sphenoidal bone, and is limited above and below by well-defined borders. In the

middle line is the shallow *sulcus basilaris* for the lodgment of the basilar artery ; this sulcus is bounded on either side by an eminence caused by the descent of the cerebrospinal fibres through the substance of the pons. Lateral to these eminences, near the upper border of the pons, the trigeminal nerves make their exit, each consisting of a smaller, medial, motor root, and a larger, lateral, sensory root ; vertical lines drawn immediately lateral to the attachments of the trigeminal nerves, may be taken as the boundaries between the ventral surface of the pons and the brachia pontis.

Its *dorsal or posterior surface*, triangular in shape, is hidden by the cerebellum, and is bounded laterally by the brachia conjunctiva ; it forms the upper part of the rhomboid fossa, with which it will be described.

Structure (fig. 745).—Transverse sections through the pons show it to be composed of two parts ; a ventral or basilar portion consisting for the most part of fibres arranged in transverse and longitudinal bundles, together with a small amount of grey substance ; and a dorsal or tegmental portion continuous with the reticular formation of the medulla oblongata, and most of the constituents of which are prolonged into the tegmenta of the cerebral peduncles.

The **basilar part** of the pons consists of : (a) superficial and deep transverse fibres, (b) longitudinal fasciculi, and (c) some small nuclei of grey substance termed the nuclei pontis.

The *superficial transverse fibres* constitute a rather thick layer on the ventral surface of the pons, and are collected into a large rounded bundle on either side. This bundle, with the addition of some transverse fibres from the deeper portion of the pons, forms the greater part of the brachium pontis.

The *deep transverse fibres* partly intersect and partly lie on the dorsal aspect of the longitudinal fasciculi. They course to the lateral border of the pons, and form part of the brachium pontis ; the further connexions of this brachium will be discussed with the anatomy of the cerebellum.

The *longitudinal fasciculi* are continued from the cerebral peduncles, and enter the upper surface of the pons. They stream downwards on either side of the middle line in bundles, separated from one another by the deep transverse fibres, and give rise to the eminences on the anterior surface. Some of these fibres end in the nuclei pontis, and others, after decussating, in the motor nuclei of the trigeminal, abducent, facial, and hypoglossal nerves ; but most of them are carried through the pons, and at its lower surface are collected into the pyramids of the medulla. The fibres which end in the motor nuclei of the cerebral nerves are derived from the pyramidal cells of the cerebral cortex, and bear the same relation to the motor cells of the cerebral nerves as the cerebrospinal fibres bear to the motor cells in the anterior column of the medulla spinalis.

The *nuclei pontis* are serially continuous with the arcuate nuclei in the medulla, and consist of small groups of multipolar nerve-cells which are scattered between the bundles of transverse fibres.

The *dorsal or tegmental part* of the pons is chiefly composed of an upward continuation of the reticular formation and grey substance of the medulla oblongata ; it is divided by a median raphe. It consists of transverse and longitudinal fibres and contains important grey nuclei. In the lower part of the pons the transverse fibres of the tegmental part are collected into a strand, named the *trapezoid body*. This consists of fibres which arise from the cells of the ventral or accessory cochlear nucleus, and will be referred to in connexion with the cochlear division of the acoustic nerve. In the substance of the trapezoid body is a collection of nerve-cells, termed the *trapezoid nucleus*. The longitudinal fibres are continuous with those of the medulla oblongata, and are mostly collected into two fasciculi on either side. One of these lies between the trapezoid body and the reticular formation, and is the upward prolongation of the *lemniscus* ; the second is situated near the floor of the fourth ventricle, and is the *medial longitudinal fasciculus*. Other longitudinal fibres, more diffusely distributed, arise from the cells of the grey substance of the pons.

The rest of the dorsal part of the pons is a continuation upwards of the formatio reticularis of the medulla oblongata, and, like it, presents the appearance of a network, in the meshes of which are numerous nerve-cells. Besides these scattered nerve-cells, there are some larger masses of grey substance,

viz. the superior olivary nucleus and the nuclei of the trigeminal, abducent, facial, and acoustic nerves (fig. 740).

1. The *superior olivary nucleus* is a small mass of grey substance situated on the dorsal surface of the lateral part of the trapezoid body. Rudimentary in man, but well developed in certain animals, it exhibits the same structure as the inferior olivary nucleus, and is situated immediately above it. Some of the fibres of the trapezoid body end by arborising around the cells of this nucleus, while others arise from these cells.

2. The *nuclei of the trigeminal nerve* in the pons are two in number : a motor and a sensory. The *motor nucleus* is situated in the upper part of the pons, close to its posterior surface and along the line of the lateral margin of the fourth ventricle. The axons of its cells form a portion of the motor root of

FIG. 745.—Coronal section of the pons, at its upper part. (Testut.)

the trigeminal nerve : the remaining fibres of the motor root of this nerve consist of a fasciculus which arises from the grey substance of the floor of the cerebral aqueduct, and hence is named the *mesencephalic root*. The *sensory nucleus* is lateral to the motor one, and beneath the brachium conjunctivum. Some of the sensory fibres of the trigeminal nerve end in this nucleus ; but the greater number descend, under the name of the spinal tract of the trigeminal nerve, to end in a nucleus which is continuous below with the substantia gelatinosa of Rolando. The motor and sensory roots of the trigeminal nerve pass through the substance of the pons and emerge near the upper margin of its anterior surface.

3. The *nucleus of the abducent nerve* is a spherical mass of grey substance situated close to the floor of the fourth ventricle, above the striæ medullares and subjacent to the medial eminence : it lies a little lateral to the ascending part of the facial nerve. The fibres of the abducent nerve pass forward through the entire thickness of the pons on the medial side of the superior olivary nucleus and between the lateral fasciculi of the cerebrospinal fibres, and emerge in the furrow between the lower border of the pons and the pyramid of the medulla oblongata.

4. The *nucleus of the facial nerve* is situated deeply in the reticular formation of the pons on the dorsal aspect of the superior olivary nucleus, and the roots of the nerve derived from it pursue a remarkably tortuous course in the substance of the pons. At first they pass backwards and medialwards until they reach the rhomboid fossa, close to the median sulcus, where they are collected into a round bundle; this bundle passes upwards and forwards, producing an elevation, the *colliculus facialis*, in the rhomboid fossa, and taking a sharp bend round the nucleus of the abducent nerve, arches lateralwards through the substance of the pons to emerge at its lower border in the interval between the olive and the restiform body of the medulla oblongata.

5. The *nuclei of the acoustic nerve*.—The acoustic nerve consists of a cochlear and a vestibular nerve. The fibres of the cochlear nerve end in two nuclei: (a) the *lateral cochlear nucleus*, on the dorsolateral surface of the restiform body; and (b) the *ventral or accessory cochlear nucleus*, on the ventral aspect of the restiform body. The nuclei in which the vestibular nerve ends are (a) the *medial or chief vestibular nucleus*, corresponding to the lower part of the area acustica in the rhomboid fossa; the caudal end of this nucleus is termed (b) the *descending or spinal vestibular nucleus*; (c) the *lateral vestibular nucleus* (nucleus of Deiters), consisting of large multipolar cells and situated in the lateral angle of the rhomboid fossa; the dorsolateral part of this nucleus is sometimes termed (d) the *superior vestibular nucleus* (nucleus of Bechterew).

Applied Anatomy.—Injury to the pons, such as may occur on the occlusion or rupture of one of its blood-vessels, often gives rise to a special train of symptoms that is almost diagnostic. Pontine lesions are characterised mainly by 'alternate paralyses'; that is to say, by paralysis of one of the motor cerebral nerves on one side, and of the limbs on the other side of the body. Thus a hæmorrhage into the lower part of the pons might cause paralysis of the face ('lower segment paralysis') on the same side, from destruction of the facial nucleus or nerve-root, and paralysis of the arm and leg on the opposite side from injury to the adjacent cerebrospinal tract. In the same way, paralysis of the Rectus lateralis of one eye and of the Rectus medialis of the other ('conjugate paralysis' of the muscles turning the two eyes in one direction) and often paralysis of one side of the face as well, together with palsy of the limbs on the opposite side of the body, may be found when the lesion occurs about the nucleus of the abducent nerve. Hearing is often unaffected in pontine lesions, possibly because the central acoustic tract occupies a ventral and lateral position in the pons.

THE CEREBELLUM

The cerebellum constitutes the largest part of the hind-brain. It lies behind the pons and medulla oblongata; between its central portion and these structures is the cavity of the fourth ventricle. It rests on the inferior fossæ of the occipital bone and is covered by the tentorium cerebelli, a fold of dura mater which separates it from the tentorial surface of the cerebrum. It is somewhat ovoid in form, but constricted medially and flattened from above downwards, its greatest diameter being from side to side. Its surface is not convoluted like that of the cerebrum, but is traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminae of which it is composed. Its average weight in the male is about 150 gms. In the adult the proportion between the cerebellum and cerebrum is about 1 to 8, in the infant about 1 to 20.

Lobes of the cerebellum.—The cerebellum consists of a median and two lateral parts. The median portion is constricted, and is called the *vermis*, from the annulated appearance of its surface; the lateral expanded portions are named the *hemispheres*. On the upper surface of the cerebellum the vermis is elevated above the level of the hemispheres, but on the under surface it is sunk almost out of sight in a deep depression between them; this depression is called the *vallecula cerebelli*, and lodges the posterior part of the medulla oblongata. The part of the vermis on the upper surface of the cerebellum is named the *superior vermis*; that on the lower surface, the *inferior vermis*. The hemispheres are separated below and behind by a deep notch, the *posterior cerebellar notch*, and in front by a broader, shallower notch, the *anterior cerebellar notch*. The posterior notch contains the upper part of the falx cerebelli, a fold

of dura mater. The anterior notch lies close to the pons and upper part of the medulla, and its superior edge encircles the inferior colliculi and the brachia conjunctiva cerebelli.

The cerebellum is characterised by its laminated or foliated appearance ; it is marked by curved fissures, which extend for a considerable distance into its substance, and divide it into a series of layers or folia. The largest and deepest fissure is named the *horizontal sulcus*. It commences in front at the pons, and passes horizontally round the free margin of the hemisphere to the middle line behind : it divides the cerebellum into an upper and a lower portion. Several secondary but deep fissures separate the cerebellum into lobes, and these are further subdivided by shallower sulci, which separate the individual folia or laminae from each other. Sections across the laminae show that the folia, though differing in appearance from the convolutions of the cerebrum, are analogous to them, inasmuch as they consist of central white substance covered by grey substance.

FIG. 746.—The superior surface of the cerebellum. (Schäfer.)

The cerebellum is connected to the cerebrum by the brachia conjunctiva, to the pons by the brachia pontis, and to the medulla oblongata by the restiform bodies.

The superior surface of the cerebellum (fig. 746) is elevated in the middle and sloped towards the circumference, the hemispheres being connected together by the superior vermis, which assumes the form of a raised median ridge, most prominent in front, but not sharply defined from the hemispheres.

The superior vermis is subdivided from before backwards into the lingula, the lobulus centralis, the monticulus and the folium vermis, and each of these, with the exception of the lingula, is continuous with corresponding parts of the hemispheres—the lobulus centralis with the alæ, the monticulus with the quadrangular lobules, and the folium vermis with the superior semilunar lobules.

The **lingula** is a small tongue-shaped process, consisting of four or five folia ; it lies in front of and is concealed by the lobulus centralis. It rests on the dorsal surface of the anterior medullary velum, and its white substance is continuous with that of the velum.

The **lobulus centralis and alæ**.—The lobulus centralis is a small square lobule, situated in the anterior cerebellar notch. It overlaps the lingula, but is separated from it by the *precentral fissure* ; laterally, it is continued into each hemisphere, as a wing-like prolongation, the *ala lobuli centralis*.

The **monticulus and quadrangular lobules**.—The monticulus is the largest part of the superior vermis. Anteriorly, it overlaps the lobulus centralis from which it is separated by the *postcentral fissure* ; laterally, it is continuous with the *quadrangular lobules* in the hemispheres. It is divided by the *preclival*

fissure into an anterior, raised part, the *culmen* or summit, and a posterior sloped part, the *clivus*; the quadrangular lobule is similarly divided. The culmen and the anterior parts of the quadrangular lobules form the *lobus culminis*; the clivus and the posterior parts, the *lobus clivi*.

The folium vermis and superior semilunar lobules.—The folium vermis (*folium caquininis*) is a short, narrow, concealed band at the posterior extremity of the superior vermis, consisting apparently of a single folium, but in reality marked on its upper and under surfaces by secondary fissures. Laterally, it expands in either hemisphere into a considerable lobule, the *superior semilunar lobule*, which occupies the posterior third of the upper surface of the hemisphere, and is bounded below by the *horizontal sulcus*. The folium vermis and the superior semilunar lobules form the *lobus semilunaris*.

The inferior surface of the cerebellum (fig. 747) presents, in the middle line, the *inferior vermis*, buried in the vallecule, and separated from the hemisphere on either side by a deep groove, the *sulcus vallecule*. This surface,

FIG. 747.—The inferior surface of the cerebellum. (Schäfer.)

like the superior, is divided into lobules; but the arrangement is more complicated, and the relations of the parts of the vermis to those of the hemispheres are less clearly marked. The inferior vermis is subdivided from before backwards, into: (1) the *nodule*, (2) the *uvula*, (3) the *pyramid*, and (4) the *tuber vermis*; the corresponding parts in the hemispheres are: (1) the *flocculus*, (2) the *tonsilla cerebelli*, (3) the *biventral lobule*, and (4) the *inferior semilunar lobule*. The three main fissures are: (1) the *postnodular fissure*, which runs transversely across the vermis, between the nodule and the uvula; in the hemispheres this fissure passes in front of the tonsilla and the biventral lobe but behind the flocculus, and joins the anterior end of the horizontal sulcus. (2) The *prepyramidal fissure* crosses the vermis between the uvula and the pyramid, then curves forwards between the tonsilla and the biventral lobe, to join the postnodular fissure. (3) The *postpyramidal fissure* passes across the vermis between the pyramid and the tuber vermis, and, in the hemisphere, courses behind the tonsilla and biventral lobule, and then along the lateral border of the biventral lobule to the postnodular sulcus; in the hemisphere it forms the anterior boundary of the inferior semilunar lobule.

The nodule, posterior medullary velum and flocculus.—The nodule, or anterior end of the inferior vermis, abuts against the roof of the fourth ventricle, and can only be distinctly seen after the cerebellum has been separated from the medulla oblongata and pons. On either side of the nodule is a thin layer of white substance, named the *posterior medullary velum*. It is semilunar in form, its convex border being continuous with the white substance

of the cerebellum; it extends on either side as far as the flocculus. The flocculus is a prominent, irregular lobule, situated in front of the biventral lobule, between it and the brachium pontis cerebelli. It is subdivided into a few small laminæ, and is connected to the posterior medullary velum by its central white core. The flocculi, nodule, and posterior medullary velum constitute the *lobus noduli*.

The uvula and tonsillæ.—The uvula forms a considerable portion of the inferior vermis; it is separated on either side from the tonsilla by the *sulcus vallecule*, at the bottom of which it is connected to the tonsilla by a furrowed ridge of grey matter called the *furrowed band*. The tonsillæ are rounded masses, situated in the hemispheres. Each lies in a deep fossa, termed the *bird's nest* (*nidus avis*), between the uvula and the biventral lobule. The uvula and tonsillæ form the *lobus uvulæ*.

The pyramid and biventral lobules constitute the *lobus pyramidalis*. The pyramid, a conical projection, is the largest prominence of the inferior vermis. It is separated from the hemispheres by the *sulcus vallecule*, across which it is connected to the biventral lobule by an indistinct grey band, analogous to the furrowed band already described. The biventral lobule is somewhat ovoid in shape; its narrower end points backwards, and is joined by the grey band to the pyramid; its broader end, directed forwards, is on a line with the anterior border of the tonsilla, and is separated from the flocculus by the postnodular fissure. The lateral border is separated from the inferior semilunar lobule by the postpyramidal fissure.

The tuber vermis and the inferior semilunar lobules form the *lobus tuberis*. The tuber vermis, the most posterior division of the inferior vermis, is of small size, and spreads out laterally into the large inferior semilunar lobules which comprise at least two-thirds of the inferior surface of the hemisphere.

INTERNAL STRUCTURE OF THE CEREBELLUM

The cerebellum consists of white and grey substance.

White substance.—If a sagittal section (fig. 748) be made through either hemisphere, the interior will be found to consist of a central stem of white substance, in the middle of which is a grey mass, the *dentate nucleus*. From this central white stem a series of plates is prolonged; these plates are covered with grey substance and form the laminæ. In consequence of the main branches from the central stem dividing and subdividing, a characteristic appearance, named the *arbor vitæ*, is presented. If the sagittal section be made through the middle of the vermis, it will be found that the central stem divides into a vertical and a horizontal branch. The vertical branch passes upwards to the culmen monticuli, where it subdivides freely, one of its ramifications passing forwards and upwards to the central lobule. The horizontal branch passes backwards to the folium vermis, greatly diminished in size in consequence of having given off large secondary branches: one, from its upper surface, ascends to the clivus monticuli; the others descend, and enter the tuber vermis, the pyramid, the uvula, and the nodule.

The white substance of the cerebellum includes two sets of nerve-fibres:

(1) *projection fibres*, (2) *fibræ propriæ*.

Projection fibres.—The cerebellum is connected to the other parts of the brain by three large bundles of projection fibres, viz. to the cerebrum by the brachia conjunctiva, to the pons by the brachia pontis, and to the medulla oblongata by the restiform bodies (fig. 749).

The brachia conjunctiva (superior cerebellar peduncles), two in number, emerge from the upper and medial part of the white substance of the hemispheres and are placed under cover of the upper part of the cerebellum. They are joined to each other across the middle line by the anterior medullary velum, and can be followed upwards as far as the inferior colliculi, under which they disappear. Below, they form the upper lateral boundaries of the fourth ventricle, but as they ascend they converge on the dorsal aspect of the ventricle and thus assist to roof it in.

The fibres of the brachium conjunctivum are mostly derived from the cells

of the dentate nucleus of the cerebellum, and emerge from the hilum of this nucleus; a few arise from the cells of the smaller grey nuclei in the cerebellar white substance, and some from the cells of the cerebellar cortex. They are continued upwards beneath the corpora quadrigemina, and the fibres of the two brachia undergo a complete decussation ventral to the cerebral aqueduct. Having crossed the middle line they divide into ascending and descending branches; the former end in the red nucleus, the thalamus, and the nucleus of the oculomotor nerve, while the latter can be traced as far as the dorsal part of the pons; Cajal believes them to be continued into the anterior funiculus of the medulla spinalis.

As already stated (p. 756), the majority of the fibres of the superficial anterolateral fasciculi of the medulla spinalis pass through the brachia conjunctiva on their way to the cerebellum.

FIG. 748.—A sagittal section of the left cerebellar hemisphere, near its junction with the vermis. (Schäfer.)

The brachia pontis (middle cerebellar peduncles) (fig. 749) are composed of centripetal fibres, which arise from the cells of the nuclei pontis of the opposite side and end in the cerebellar cortex; the fibres are arranged in three fasciculi, superior, inferior, and deep. The *superior* fasciculus is derived from the upper transverse fibres of the pons; it is directed backwards and lateralwards superficially to the other two fasciculi, and is distributed mainly to the lobules on the inferior surface of the cerebellar hemisphere, and to the parts of the superior surface adjoining the posterior and lateral margins. The *inferior* fasciculus is formed by the lowest transverse fibres of the pons; it passes under cover of the superior fasciculus and is continued downwards and backwards more or less parallel with it, to be distributed to the folia on the under surface close to the vermis. The *deep* fasciculus comprises most of the deep transverse fibres of the pons. It is at first covered by the superior and inferior fasciculi, but crossing obliquely it appears on the medial side of the superior, from which it receives a bundle; its fibres spread out and pass to the upper anterior cerebellar folia. The fibres of this fasciculus cover those of the restiform body.*

The restiform bodies (inferior cerebellar peduncles) pass at first upwards and lateralwards, forming part of the lateral walls of the fourth ventricle, and

* See article by E. B. Jamieson, *Journal of Anatomy and Physiology*, vol. xlii.

then bend abruptly backwards to enter the cerebellum between the brachia conjunctiva and brachia pontis. Each contains the following fasciculi: (1) the direct cerebellar tract of the medulla spinalis, which ends mainly in the superior vermis; (2) fibres from the nucleus gracilis and nucleus cuneatus, of the same and of the opposite sides; (3) fibres from the opposite inferior olivary nucleus; (4) crossed and uncrossed fibres from the reticular formation of the medulla oblongata; (5) vestibular fibres, derived partly from the vestibular division of the acoustic nerve and partly from the nuclei in which this division ends—these fibres occupy the medial segment of the restiform body and divide into ascending and descending branches; the ascending branches partly end in the roof nucleus of the opposite side of the cerebellum; (6) cerebellobulbar fibres which come from the opposite roof nucleus and probably from the dentate nucleus, and are said to end in the nucleus of Deiters and in the formatio reticularis of the medulla oblongata.

FIG. 749.—A dissection showing the projection fibres of the cerebellum.
(E. B. Janieson.)

The **anterior medullary velum** (valve of Vieussens) is a thin, transparent lamina of white substance, which stretches between the brachia conjunctiva; the folia of the lingula are prolonged on to the dorsal surface of its lower half. It forms, together with the brachia conjunctiva, the roof of the upper part of the fourth ventricle; it is narrow above, where it passes beneath the inferior colliculi, and broader below, where it is continuous with the white substance of the superior vermis. A median ridge, the *frenulum veli*, descends upon its upper part from between the inferior colliculi, and on either side of the frenulum the trochlear nerve emerges.

The **posterior medullary velum** is a thin layer of white substance, above and on either side of the nodule; it forms a part of the roof of the fourth ventricle. Somewhat semilunar in shape, its convex edge is continuous with the white substance of the cerebellum, while its thin concave margin is apparently free; in reality, however, it is continuous with the epithelium of the ventricle, which is prolonged downwards from the posterior medullary velum to the tæniæ of the fourth ventricle.

The two medullary vela are in contact with each other along their line of emergence from the white substance of the cerebellum; and this line of contact forms the *fastigium* or summit of the roof of the fourth ventricle, which, in a sagittal section through the cavity, appears as a pointed angle.

The *fibræ propriæ* of the cerebellum are of two kinds: (1) *commissural fibres*, which cross the middle line at the anterior and posterior parts of the vermis and connect the opposite halves of the cerebellum; (2) *arcuate or association fibres*, which connect adjacent lobules and laminæ with each other.

Grey substance.—The grey substance of the cerebellum is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

(1) The **grey substance of the cortex** presents a characteristic foliated appearance, due to the series of laminæ which project from the central white substance; these in their turn give off secondary laminæ, which are covered by grey substance. Externally the cortex is covered by pia mater; internally it rests on the white substance.

Microscopic appearance of the cortex (fig. 750).—The cortex consists of two layers, viz. an external grey, or molecular, layer, and an internal rust-coloured, or nuclear, layer; between these is an incomplete stratum of cells, the *cells of Purkinje*.

The *external grey, or molecular, layer* consists of nerve-fibres and cells. The fibres comprise: (a) the dendrites and axon-collaterals of Purkinje's cells; (b) fibres from cells in the nuclear layer; (c) fibres from the central white substance of the cerebellum; (d) fibres derived from cells in the molecular layer itself. In addition to these are other fibres, which have a vertical direction and are the processes of large neuroglia cells situated in the nuclear layer. They pass outwards to the periphery of the grey substance, where they expand into little conical enlargements which form a sort of limiting membrane beneath the pia mater, analogous to the *membrana limitans interna* of the retina.

The *cells of the molecular layer* are small, and are arranged in an inner and an outer layer; they all possess branched axons. The cells of the inner layer are termed *basket-cells*; their axons run for some distance parallel with the surface of the folium and give off collaterals which form basket-like networks around the bodies of Purkinje's cells.

The *cells of Purkinje* are peculiar to the cerebellum; they form a single stratum of large, flask-shaped cells at the junction of the molecular and nuclear layers, their bases resting against the latter. The cells are flattened in a direction transverse to the long axis of the folium, and thus appear broad in sections carried across the folium, and fusiform in sections parallel to the long axis of the folium. From the neck of the flask one or more dendrites arise and pass into the molecular layer, where they subdivide and form an extremely rich arborescence, the various subdivisions of the dendrites being covered by lateral spine-like processes. This arborescence, like the cell, is flattened at right angles to the long axis of the folium; in other words, it resembles the branches of a fruit-tree trained against a trellis or a wall. Hence, in sections carried across the folium the arborescence is broad and expanded; whereas in sections parallel to the long axis of the folium, the arborescence, like the cell, is seen in profile, and is limited to a narrow area.

From the bottom of the flask-shaped cell the axon arises; this passes through the nuclear layer, and, becoming medullated, is continued as a nerve-fibre in the subjacent white substance. As it traverses the nuclear layer it gives off fine collaterals, some of which run into the molecular layer.

The *internal rust-coloured, or nuclear, layer* (fig. 750) contains numerous small nerve-cells of a reddish-brown colour, together with many nerve-fibrils. Most of the cells are nearly spherical and provided with short dendrites which spread out in a spider-like manner in the nuclear layer. Their axons pass into the molecular layer, and, bifurcating at right angles, run for some distance parallel to the long axis of the folium. In the outer part of the nuclear layer are some larger cells, of the type II. of Golgi. Their axons undergo frequent division as soon as they leave the nerve-cells, and pass into the nuclear layer; while their dendrites ramify chiefly in the molecular layer.

Finally, in the grey substance of the cerebellar cortex, there are fibres which come from the white centre and penetrate the cortex. The cell-origin of these fibres is unknown, but is probably in the grey substance of the medulla spinalis. Some of them end in the nuclear layer by dividing into numerous

branches, on which are to be seen peculiar moss-like appendages; hence they have been termed by Ramón y Cajal the *moss-fibres*; they form an arborescence around the cells of the nuclear layer. Other fibres, the *clinging* or *tendrill fibres*, can be traced into the molecular layer, where their branches cling around the dendrites of Purkinje's cells.

(2) The independent centres of grey substance are imbedded in the white substance of the cerebellum, and are four in number on either side: one is of large size, and is known as the nucleus dentatus; the other three,

FIG. 750.—A transverse section of a cerebellar folium. (Diagrammatic, after Ramón y Cajal and Kölliker.)

much smaller, are situated near the middle of the cerebellum, and are known as the nucleus emboliformis, nucleus globosus, and nucleus fastigii.

The *nucleus dentatus* (fig. 751) is situated a little to the medial side of the centre of the stem of the white substance of the hemisphere. It consists of an irregularly folded lamina, of a greyish-yellow colour, containing white fibres, and presenting on its anteromedial aspect an opening, the hilum, from which most of the fibres of the brachium conjunctivum emerge (p. 778).

The *nucleus emboliformis* lies close to the medial side of the nucleus dentatus, and partly covering its hilum. The *nucleus globosus*, an elongated mass, lies medially to the nucleus emboliformis, and is directed anteroposteriorly. The *nucleus fastigii* is somewhat larger than the other two, and is situated

close to the middle line at the anterior end of the superior vermis, and immediately over the roof of the fourth ventricle, from which it is separated by a thin layer of white substance.

Applied Anatomy.—The general functions of the cerebellum in the human appear to be the co-ordination of movements, and equilibration. The exact functions of its different parts are still quite uncertain, owing to the contradictory nature of the evidence furnished by (1) ablation experiments upon animals, and (2) clinical observations in man of the effects produced by abscesses or tumours affecting different portions of the organ. According to W. Aldren Turner, 'The following localising symptoms would therefore indicate the presence of a tumour implicating the right cerebellar hemisphere

FIG. 751.—A sagittal section through the right cerebellar hemisphere. The right olive has also been cut sagittally.

and middle peduncle: deafness in the right ear, associated with middle ear complications; and unsteady and uncertain gait with a tendency to fall more particularly to the right side; coarse nystagmoid oscillations on looking to the right; movements resembling those of disseminated sclerosis on voluntary effort of the right arm; an awkward uncertain action of the right leg; a slight increase of the right knee-jerk; and, perhaps, slight blunting of sensibility over the right cornea and side of the face.'

THE FOURTH VENTRICLE

The fourth ventricle, or cavity of the rhombencephalon, is situated in front of the cerebellum, and behind the pons and upper half of the medulla oblongata. Developmentally considered, it consists of three parts: a *superior* belonging to the isthmus rhombencephali, an *intermediate*, to the metencephalon, and an *inferior*, to the myelencephalon. It is lined by ciliated epithelium, and is continuous below with the central canal of the medulla oblongata*; above, it communicates, by means of a passage termed the cerebral aqueduct, with the cavity of the third ventricle. It presents four angles and possesses a roof or dorsal wall, a floor or ventral wall (rhomboid fossa), and lateral boundaries.

Angles.—The *superior angle* is on a level with the upper border of the pons, and is continuous with the lower end of the cerebral aqueduct. The *inferior angle* is on a level with the lower end of the olive, and opens into the central canal of the medulla oblongata. Each *lateral angle* corresponds with the point of meeting of the brachium conjunctivum and restiform body. A little

* J. T. Wilson (*Journal of Anatomy and Physiology*, vol. xl.) has pointed out that the central canal of the medulla oblongata, immediately below its entrance into the fourth ventricle, retains the cleft-like form presented by the canal in the fetal medulla spinalis, and that it is marked by dorsolateral and ventrolateral sulci.

below the lateral angles, on a level with the *striae medullares*, the ventricular cavity is prolonged outwards in the form of two narrow *lateral recesses*, one on either side; these are situated between the restiform bodies and the cerebellopontine angle, and reach as far as the attachments of the glossopharyngeal and vagus nerves.

Lateral boundaries.—The lower part of each lateral boundary is constituted by the clava, the fasciculus cuneatus, and the restiform body; the upper part by the brachium pontis and the brachium conjunctivum.

Roof or dorsal wall (fig. 752).—The upper portion of the roof is formed by the brachia conjunctiva and the anterior medullary velum; the lower portion, by the posterior medullary velum, the epithelial lining of the ventricle covered by the tela chorioidea inferior, the tæniæ of the fourth ventricle, and the obex.

The *brachia conjunctiva* (p. 778), on emerging from the central white substance of the cerebellum, pass upwards and forwards, forming at first the

FIG. 752.—A scheme of the roof of the fourth ventricle. The arrow is in the foramen of Majendie.

lateral boundaries of the upper part of the ventricle; on approaching the inferior colliculi, they converge, and their medial portions overlap the ventricle and form part of its roof.

The *anterior medullary velum* (p. 780) fills in the angular interval between the brachia conjunctiva, and is continuous behind with the central white substance of the cerebellum; it is covered on its dorsal surface by the lingula of the superior vermis.

The *posterior medullary velum* (p. 780) is continued downwards and forwards from the central white substance of the cerebellum in front of the nodule and tonsillæ, and ends inferiorly in a thin, concave, somewhat ragged margin. Below this margin the roof of the ventricle is devoid of nervous matter except in the immediate vicinity of the lower lateral boundaries of the ventricle, where two narrow white bands, the *tæniæ of the fourth ventricle*, appear; these bands meet over the inferior angle of the ventricle in a thin triangular lamina, the *obex*. The non-nervous part of the roof is formed by the *epithelial lining of the ventricle*, which is prolonged downwards as a thin membrane, from the deep surface of the posterior medullary velum to the corresponding surface of the obex and tæniæ, and thence on to the floor of the ventricular cavity; it is covered and strengthened by a portion of the pia mater which is named the *tela chorioidea of the fourth ventricle*.

The *tæniæ of the fourth ventricle* (ligules) are two narrow bands of white matter, one on either side, which complete the lower part of the roof of the ventricle. Each consists of a vertical and a horizontal part. The vertical part is continuous with the clava, to which it is adherent by its lateral border. The horizontal portion extends transversely across the restiform body, below the stria medullares, and roofs in the lower and posterior part of the lateral recess; it is attached by its lower margin to the restiform body, and partly encloses the choroid plexus, which, however, projects beyond it like a cluster of grapes; and hence this part of the tænia has been termed the *cornucopia* (Bochdalek). The *obex* is a thin, triangular, grey lamina, which roofs in the lower angle of the ventricle and is attached by its lateral margins to the clavæ.* The *tela chorioidea of the fourth ventricle* is the name applied to the triangular fold of pia mater which is carried upwards between the cerebellum and the medulla oblongata. It consists of two layers, which are continuous with each other in front, and are more or less adherent throughout. The posterior layer covers the antero-inferior surface of the cerebellum, while the anterior is applied to the structures which form the lower part of the roof of the ventricle, and is continuous inferiorly with the pia mater on the restiform bodies and the closed part of the medulla.

Choroid plexuses.—Two highly vascular fringe-like processes of the tela chorioidea are named the choroid plexuses of the fourth ventricle; they invaginate the lower part of the roof of the ventricle and are everywhere covered by the epithelial lining of the cavity. Each consists of a vertical and a horizontal portion: the former lies close to the middle line, and the latter passes into the lateral recess and projects beyond its apex. The vertical parts of the plexuses are distinct from each other, but the horizontal portions are joined in the middle line; and hence the entire structure presents the form of the letter T, the vertical limb of which, however, is double.

Openings in the roof.—In the roof of the fourth ventricle there are three openings, a medial and two lateral: the medial aperture (*foramen Majendii*) is situated immediately above the inferior angle of the ventricle; the lateral apertures are found at the extremities of the lateral recesses. Through these openings the ventricular cavity communicates with the subarachnoid cavity, and the cerebrospinal fluid can circulate from the one cavity to the other.

Rhomboid fossa (fig. 753).—The anterior wall or floor of the fourth ventricle is named, from its shape, the rhomboid fossa; it is formed by the posterior surface of the pons and medulla oblongata. It is covered by a thin layer of grey substance continuous with that of the medulla spinalis; superficial to this is a thin lamina of neuroglia which constitutes the ependyma of the ventricle and supports a layer of ciliated epithelium. The fossa consists of three parts, superior, intermediate, and inferior. The *superior* part is triangular in shape and limited laterally by the brachia conjunctiva cerebelli; its apex, directed upwards, is continuous with the cerebral aqueduct; its base is represented by an imaginary line at the level of the upper ends of two small depressions, named the *superior foveæ*. The *intermediate* part extends from this level to that of the horizontal portions of the tæniæ of the ventricle; it is narrow above where it is limited laterally by the brachia pontis, but widens below and is prolonged into the lateral recesses of the ventricle. The *inferior* part is triangular, and its downwardly directed apex, named the *calamus scriptorius*, is continuous with the wall of the central canal of the closed part of the medulla oblongata.

The rhomboid fossa is divided into symmetrical halves by a *median sulcus* which reaches from the upper to the lower angle of the fossa and is deeper below than above. On either side of this sulcus is an elevation, the *medial eminence*, bounded laterally by a sulcus, the *sulcus limitans*. In the superior part of the fossa the medial eminence has a width equal to that of the corresponding half of the fossa, but opposite the superior fovea it forms an elongated swelling, the *colliculus facialis*, which overlies the nucleus of the abducens

*J. T. Wilson, *loc. cit.*, recognises two forms of obex: (a) the *true obex*, constituted by a medullary thickening of the roof-plate, and (b) a *false or membranous obex* where the medullary thickening fails, and the roof-plate is represented only by the ependymal layer clothing the ventral surface of a pia reduplication which forms the main substance of the membranous fold in question.

nerve, and is in part produced by the ascending portion of the root of the facial nerve. In the inferior part of the fossa the medial eminence assumes the form of a triangular area, the *trigonum hypoglossi*. When examined under water with a lens the trigonum hypoglossi is seen to consist of a medial and a lateral area separated by a series of oblique furrows; the medial area corresponds with the upper part of the nucleus of the hypoglossal nerve, the lateral with a small nucleus, the *nucleus intercalatus*.

The *sulcus limitans* forms the lateral boundary of the medial eminence. Its superior part corresponds with the lateral limit of the fossa and presents a bluish-grey area, the *locus cæruleus*, which owes its colour to a patch of deeply

FIG. 753.—The rhomboid fossa.

pigmented nerve-cells, termed the *substantia ferruginea*. At the level of the colliculus facialis the sulcus limitans widens into a flattened depression, the *superior fovea*, and in the inferior part of the fossa appears as a distinct dimple, the *inferior fovea*. Lateral to the foveæ is a rounded elevation named the *area acustica* which extends into the lateral recess. Winding round the restiform body and crossing the area acustica and the medial eminence are a number of white strands, the *stria medullares* (*stria acusticæ*), which form a portion of the cochlear division of the acoustic nerve and disappear into the median sulcus. Below the inferior fovea, and between the trigonum hypoglossi and the lower part of the area acustica, is a triangular dark field, the *ala cinerea*, in which the sensory fibres of the vagus and glossopharyngeal nerves end. The lower end of the ala cinerea is crossed by a narrow translucent ridge, the *funiculus separans*, and between this funiculus and the clava is a small tongue-shaped area, the *area postrema*. On section it is seen that the funiculus separans is formed by a strip of thickened ependyma, and the area postrema by loose, highly vascular, neuroglial tissue containing nerve-cells of moderate size.

THE MESENCEPHALON OR MID-BRAIN

The mesencephalon or mid-brain is the short, constricted portion which connects the pons and cerebellum with the thalamencephalon and cerebral hemispheres. It is directed upwards and forwards, and consists of (1) a ventrolateral portion, composed of a pair of cylindrical bodies, named the *cerebral peduncles*; (2) a dorsal portion, consisting of four rounded eminences, named the *corpora quadrigemina*; and (3) an intervening passage or tunnel, the *cerebral aqueduct*, which represents the original cavity of the mid-brain and connects the third and fourth ventricles (fig. 754).

The cerebral peduncles (*crura cerebri*) are two cylindrical masses situated at the base of the brain, and largely hidden by the temporal lobes of the cerebrum, which must be drawn aside or removed in order to expose them. They emerge from the upper surface of the pons, one on either side of the middle line, and, diverging as they pass upwards and forwards, disappear into the substance of the cerebral hemispheres. The depressed area between the diverging cerebral peduncles is termed the *interpeduncular fossa*, and consists of a layer of greyish substance, the *posterior perforated substance*, which is pierced by small apertures for the transmission of blood-vessels. The lower part of the posterior perforated substance lies on the ventral aspect of the tegmenta, and contains a nucleus named the *interpeduncular ganglion* (p. 790); its upper part assists in forming the floor of the third ventricle.

The ventral surface of each peduncle is crossed behind, from the medial to the lateral side, by the superior cerebellar and posterior cerebral arteries, while, close to the point of disappearance of the peduncle into the cerebral hemisphere, the optic tract winds forwards around it. The medial surface of the peduncle forms the lateral boundary of the interpeduncular fossa, and is marked by a longitudinal furrow, the *oculomotor sulcus*, from which the roots of the oculomotor nerve emerge. The lateral surface of the peduncle is in relation to the gyrus hippocampi of the cerebral hemisphere and is crossed from behind forwards by the trochlear nerve. Running along it, is a longitudinal furrow, termed the *lateral sulcus*; the fibres of the lateral lemniscus come to the surface in this sulcus, and pass backwards and upwards, to disappear under the inferior colliculus.

Structure of the cerebral peduncles (figs. 755, 756).—On transverse section, each peduncle is seen to consist of a dorsal and a ventral part, separated by a deeply pigmented lamina of grey substance, termed the *substantia nigra*. The dorsal part is named the *tegmentum*; the ventral, the *base* or *crusta*. The bases of the peduncles are separated from each other, but the tegmenta are joined in the median plane by a forward prolongation of the raphe of the pons. Laterally, the tegmenta are free; dorsally, they blend with the *corpora quadrigemina*.

NEUROLOGY

The base (*crusta* or *pes*) is semilunar on transverse section, and consists almost entirely of longitudinal bundles of efferent fibres which arise from the cells of the cerebral cortex and are grouped into three principal sets, viz. cerebrospinal, frontopontine, and temporopontine (fig. 754). The *cerebrospinal* fibres are derived from the cells of the motor area of the cerebral cortex and occupy the middle three-fifths of the base; some of them end in the nuclei

FIG. 755.—A transverse section of the mid-brain at the level of the inferior colliculi.

FIG. 756.—A transverse section of the mid-brain at the level of the superior colliculi.

of the motor cerebral nerves of the opposite side, but most of them pass into the pyramids of the medulla oblongata. The *frontopontine* fibres are situated in the medial fifth of the base; they arise from the cells of the frontal lobe and end in the nuclei of the pons. The *temporopontine* fibres are lateral to the cerebrospinal fibres; they originate in the temporal lobe and end in the nuclei of the pons.*

* A band of fibres, the *tractus peduncularis transversus*, is sometimes seen emerging from in front of the superior colliculus; it passes round the ventral aspect of the peduncle about midway between the pons and the optic tract, and dips into the oculomotor sulcus. This band is a constant structure in many mammals, but is only present in about thirty per cent. of human brains. Since it undergoes atrophy after enucleation of the eyeballs, it may be considered as forming a path for visual sensations.

The *substantia nigra* is a layer of grey substance containing numerous deeply pigmented, multipolar nerve-cells. It is semilunar on transverse section, its concavity being directed towards the tegmentum; from its convexity, processes of it extend between the fibres of the base of the peduncle. Thicker medially than laterally, it reaches from the oculomotor sulcus to the lateral sulcus, and extends from the upper surface of the pons to the subthalamic region; its medial part is traversed by the fibres of the oculomotor nerve as these stream forwards to reach the oculomotor sulcus. The connexions of the cells of the *substantia nigra* have not been definitely established.

FIG. 757.—A scheme of the medial longitudinal fasciculus; motor fibres in red, sensory fibres in blue.

The *tegmentum* is continuous below with the reticular formation of the pons, and, like it, consists of a considerable amount of grey substance together with longitudinal and transverse fibres. The principal grey masses of the tegmentum are the red nucleus and the interpeduncular ganglion; of its fibres the chief longitudinal tracts are the brachium conjunctivum, the medial longitudinal fasciculus, and the lemniscus.

Grey substance.—The *red nucleus* is situated in the anterior part of the tegmentum, and is continued upwards into the posterior part of the subthalamic region. In sections at the level of the superior colliculus it appears as a circular mass which is traversed by the fibres of the oculomotor nerve. Most of the fibres of the brachium conjunctivum end in this nucleus (p. 778). The axons of its larger cells cross the middle line and are continued downwards into the lateral funiculus of the medulla spinalis as the rubrospinal tract (p. 755); those of its smaller cells end mainly in the thalamus.

The *interpeduncular ganglion* is a median collection of nerve-cells situated in the ventral part of the tegmentum. The fibres of the fasciculus retroflexus of Meynert, which have their origin in the cells of the ganglion habenulæ (p. 797), end in the interpeduncular ganglion.

Besides the two nuclei mentioned, there are small collections of nerve-cells which form the dorsal and ventral nuclei and the central nucleus or nucleus of the raphe.

White substance.—(1) The origin and course of the *brachium conjunctivum* have already been described (p. 778).

(2) The *medial (posterior) longitudinal fasciculus* (fig. 757) is continuous below with the proper fasciculi of the anterior and lateral funiculi of the medulla spinalis; and has been traced by Edinger as far as a nucleus, the *nucleus of the*

FIG. 758.—Transverse section passing through the sensory decussation (decussation of the lemniscus). (Schematic.) (Testut.)

through the medial longitudinal fasciculus from the nucleus of the abducent nerve into the oculomotor nerve of the opposite side, and through this nerve to the Rectus medialis oculi. Fibres are said to be prolonged through this fasciculus from the nucleus of the oculomotor nerve into the facial nerve, and distributed to the Orbicularis oculi, the Corrugator, and the Frontalis.*

The fibres of the *lemniscus* or *fillet* (fig. 759) take origin in the nucleus gracilis and nucleus cuneatus of the medulla oblongata, and cross to the opposite side in the sensory decussation (p. 767). They then pass upwards through the medulla oblongata, in which they are situated behind the cerebrospinal fibres and between the olives. Here they are joined by the fibres of the superficial anterolateral fasciculus, these having already undergone decussation in the medulla spinalis. As the lemniscus ascends, it receives additional fibres from the terminal nuclei of the sensory cerebral nerves of the opposite side. In the pons, it assumes a flattened, ribbon-like appearance, and is placed dorsal to the trapezium. In the mesencephalon, its lateral part is folded backwards and forms nearly a right angle with its medial portion; and hence it is customary to speak of a lateral and a medial lemniscus.

The *lateral lemniscus* comes to the surface in the lateral sulcus, and disappears under the inferior colliculus. It consists of fibres from the terminal nuclei of the cochlear division of the acoustic nerve, together with others from the superior olivary and trapezoid nuclei. Most of these fibres are crossed,

* Bruce and Pirie ('On the Origin of the Facial Nerve,' *Review of Neurology and Psychiatry*, vol. vi. No. 12, December 1908) produce weighty evidence against the view that the facial nerve derives fibres from the nucleus of the oculomotor nerve.

but some are uncrossed; they end in the inferior colliculus and the medial geniculate body.

The *medial lemniscus* begins in the nucleus gracilis and nucleus cuneatus of the opposite side, and is joined by the superficial anterolateral fasciculus of the medulla spinalis and by fibres from the terminal nuclei of the sensory cerebral nerves of the opposite side, excepting the cochlear division of the acoustic nerve. In the cerebral peduncle, a few of its fibres pass upwards in

FIG. 759.—A scheme showing the course of the fibres of the lemniscus; medial lemniscus in blue, lateral in red.

the lateral part of the base of the peduncle on the dorsal aspect of the temporo-pontine fibres, and reach the lentiform nucleus and the insula. With this exception the fibres of the medial lemniscus are prolonged through the tegmentum into the thalamus, around the cells of which they form arborisations. From the cells of the thalamus a relay of fibres is prolonged to the cerebral cortex.

In the tegmentum there are, besides these three tracts, the *tectospinal fasciculus* from the superior colliculus, and the *rubrospinal fasciculus* from the red nucleus; these cross the middle line and are continued downwards into the medulla spinalis (p. 755).

The *corpora quadrigemina* (fig. 763) are four rounded eminences which form the dorsal part of the mesencephalon. They are situated above and

in front of the anterior medullary velum and brachia conjunctiva, and below and behind the third ventricle and posterior commissure. They are covered by the splenium of the corpus callosum, and are partly overlapped on either side by the medial angle, or pulvinar, of the posterior end of the thalamus. The corpora quadrigemina are arranged in pairs (superior and inferior colliculi), and are separated from one another by a crucial sulcus. The longitudinal part of this sulcus expands superiorly to form a slight depression which supports the *pineal body*, a cone-like structure which projects backwards from the thalamencephalon and partly obscures the superior colliculi. From the inferior end of the longitudinal sulcus a white band, termed the *frenulum veli*, is prolonged downwards to the anterior medullary velum; on either side of this band the trochlear nerve emerges, and passes forwards on the lateral aspect of the cerebral peduncle to reach the base of the brain. The *superior colliculi* are larger and darker in colour than the inferior, and are oval in shape. The *inferior colliculi* are hemispherical, and somewhat more prominent than the superior. The superior colliculi are associated with the sense of sight, the inferior with that of hearing.

From the lateral aspect of each colliculus a white band, termed the *brachium*, is prolonged, upwards and forwards. The *superior brachium* extends laterally from the superior colliculus, and, passing between the pulvinar and medial geniculate body, is partly continued into an eminence called the lateral geniculate body, and partly into the optic tract. The *inferior brachium* passes forwards and upwards from the inferior colliculus and disappears under cover of the medial geniculate body.

In close relationship with the corpora quadrigemina are the brachia conjunctiva, which emerge from the upper and medial parts of the cerebellar hemispheres. They run upwards and forwards, and, passing under the inferior colliculi, enter the tegmenta as already described (p. 778).

Structure of the corpora quadrigemina.—The *inferior colliculus* consists of a compact nucleus of grey substance containing large and small multipolar nerve-cells, and is more or less completely surrounded by fibres derived from the lateral lemniscus; most of these fibres end in the grey nucleus of the same side, but some cross the middle line and end in that of the opposite side. From the cells of the grey nucleus, fibres are prolonged through the inferior brachium into the tegmentum of the cerebral peduncle, and are carried to the thalamus and the cortex of the temporal lobe; other fibres cross the middle line and end in the opposite colliculus.

The *superior colliculus* is covered by a thin stratum (*stratum zonale*) of white fibres, the majority of which are derived from the optic tract. Beneath this is the *stratum cinereum*, a cap-like layer of grey substance, thicker in the centre than at the circumference, and consisting of numerous small multipolar nerve-cells imbedded in a fine network of nerve-fibres. Still deeper is the *stratum opticum*, containing large multipolar nerve-cells separated by numerous fine nerve-fibres. Finally, there is the *stratum lemnisci*, consisting of fibres derived partly from the lemniscus and partly from the cells of the stratum opticum; interspersed among these fibres are many large multipolar nerve-cells. Of the afferent fibres which reach the superior colliculus, some are derived from the lemniscus, but the majority have their origins in the retina and are conveyed to the superior colliculus through the superior brachium; all of them end by arborising around the cells of the grey substance. Of the efferent fibres, some cross the middle line to the opposite colliculus; many ascend through the superior brachium, and finally reach the cortex of the occipital lobe of the cerebrum; while others, after undergoing decussation (*fountain decussation of Meynert*) form the tectospinal fasciculus which descends through the formatio reticularis of the mesencephalon, pons, and medulla oblongata into the medulla spinalis, where it is found partly in the anterior funiculus and partly intermingled with the fibres of the rubrospinal tract.

The corpora quadrigemina are larger in the lower animals than in man. In fishes, reptiles, and birds, they are hollow, and only two in number (corpora bigemina); they represent the superior colliculi of mammals, and are frequently termed the optic lobes, because of their intimate connexion with the optic tracts.

The **cerebral aqueduct** (**aqueduct of Sylvius**) is a narrow canal, about 15 mm. long, situated between the corpora quadrigemina and tegmenta, and connecting the third with the fourth ventricle. Its form, as seen in transverse sections, varies at different levels, being T-shaped below, triangular above, and oval in the middle; its central part is slightly dilated, and was named by Retzius the *ventricle of the mid-brain*. It is lined by ciliated columnar epithelium, and is surrounded by a layer of grey substance named the *central grey stratum*; this is continuous below with the grey substance in the rhomboid fossa, and above with that of the third ventricle. Dorsally, the aqueduct is partly separated from the grey substance of the quadrigeminal bodies by the fibres of the lemnisci; ventral to it are the medial longitudinal fasciculus, and the formatio reticularis of the tegmentum. Scattered throughout the central grey stratum are numerous nerve-cells of various sizes, interlaced by a network of fine fibres. Besides these scattered cells it contains three groups which constitute the nucleus of the mesencephalic root of the trigeminal nerve and the nuclei of the oculomotor and trochlear nerves. The *nucleus of the trigeminal nerve* extends along the entire length of the aqueduct, and occupies the lateral part of the grey stratum, while the nuclei of the oculomotor and trochlear nerves are situated in its ventral part. The *nucleus of the oculomotor nerve* is about 10 mm. long, and lies mainly under the superior colliculus, beyond which, however, it extends for a short distance into the grey substance of the third ventricle. The *nucleus of the trochlear nerve* is small and nearly circular, and is on a level with a plane carried transversely through the upper part of the inferior colliculus.

THE PROSENCEPHALON OR FORE-BRAIN

The **prosencephalon** or **fore-brain** consists of: (1) the *diencephalon*, corresponding in a large measure to the third ventricle and the structures which bound it; and (2) the *telencephalon*, comprising the largest part of the brain, viz. the cerebral hemispheres; these hemispheres are connected with each other across the middle line, and each contains a large cavity, named the lateral ventricle. The lateral ventricles communicate through the inter-ventricular foramen with the third ventricle, but are separated from each other by a median septum, the septum pellucidum; this contains a slit-like cavity, which does not communicate with the ventricles.

THE DIENCEPHALON

The **diencephalon** is connected above and in front with the cerebral hemispheres; behind with the mesencephalon. Its upper surface is concealed by the corpus callosum, and is covered by a fold of pia mater, named the tela chorioidea of the third ventricle; inferiorly it reaches to the base of the brain.

The diencephalon comprises: (1) the thalamencephalon; (2) the pars mamillaris hypothalami; and (3) the posterior part of the third ventricle. For descriptive purposes, however, it is more convenient to consider the whole of the third ventricle and its boundaries together: this necessitates the inclusion, under this heading, of the pars optica hypothalami and the corresponding part of the third ventricle—structures which properly belong to the telencephalon.

The **thalamencephalon** comprises: (1) the thalamus; (2) the metathalamus or corpora geniculata; and (3) the epithalamus, consisting of the trigonum habenulae, the pineal body, and the posterior commissure.

The **thalami** (figs. 760, 761) are two large ovoid masses, situated one on either side of the third ventricle and reaching for some distance behind that cavity. Each measures about 4 cm. in length, and presents two extremities, an anterior and a posterior, and four surfaces, superior, inferior, medial, and lateral.

The *anterior extremity* is narrow ; it lies close to the middle line and forms the posterior boundary of the interventricular foramen.

The *posterior extremity* is expanded, directed backwards and lateralwards, and overlaps the superior colliculus. Medially, this extremity presents an angular prominence, the *pulvinar*, which is continued laterally into an oval swelling, the *lateral geniculate body*, while beneath the pulvinar, but separated from it by the superior brachium, is a second oval swelling, the *medial geniculate body*.

The *superior surface* is free, slightly convex, and covered by a layer of white substance, termed the *stratum zonale*. It is separated laterally from the ventricular surface of the caudate nucleus by a white band, the *stria terminalis*, and by the terminal vein. It is divided into a medial and a lateral

FIG. 760.—A dissection showing the ventricles of the brain.

portion by an oblique shallow furrow which runs from behind forwards and medialwards and corresponds with the lateral margin of the fornix ; the lateral part forms a portion of the floor of the lateral ventricle, and is covered by the epithelial lining of this cavity ; the medial part is covered by the tela chorioidea of the third ventricle, and is destitute of an epithelial covering. In front, the superior is separated from the medial surface by a salient margin, the *tænia thalami*, along which the epithelial lining of the third ventricle is reflected on to the under surface of the tela chorioidea. Behind, it is limited medially by a groove, the *sulcus habenulae*, which intervenes between it and a small triangular area termed the *trigonum habenulae*.

The *inferior surface* rests upon and is continuous with the upward prolongation of the tegmentum (*subthalamie tegmental region*), in front of which it is related to the *substantia innominata* of Meynert (p. 822).

The *medial surface* constitutes the upper part of the lateral wall of the third ventricle, and is connected to the corresponding surface of the opposite thalamus by a flattened grey band, the *massa intermedia* (middle or grey

commissure). This mass lies close behind the interventricular foramen, and averages about 1 cm. in its anteroposterior diameter: it sometimes consists of two parts, and occasionally is absent. It contains nerve-cells and nerve-fibres: a few of the latter may cross the middle line, but most of them pass towards the middle line and then curve lateralwards on the same side.

The *lateral surface* is in contact with a thick band of white substance which forms the occipital part of the internal capsule and separates the thalamus from the lentiform nucleus of the corpus striatum.

FIG. 761.—A coronal section of the brain immediately in front of the pons.

Structure.—The thalamus consists chiefly of grey substance, but its upper surface is covered by a layer of white substance, named the *stratum zonale*, and its lateral surface by a similar layer termed the *lateral medullary lamina*. Its grey substance is incompletely subdivided into three parts—*anterior*, *medial*, and *lateral*—by a white layer, the *medial medullary lamina*. The anterior part comprises the anterior tubercle, the medial part lies next the lateral wall of the third ventricle, while the lateral and largest part is interposed between the medullary laminae and includes the pulvinar. The lateral part is traversed by numerous fibres which radiate from the thalamus into the internal capsule, and pass through the latter to the cerebral cortex. These three parts are built up of numerous nuclei, the connexions of many of which are imperfectly known.

Connexions.—The thalamus may be regarded as a large ganglionic mass in which the ascending tracts of the tegmentum and a considerable proportion of the fibres of the optic tract end, and from the cells of which numerous fibres

(thalamocortical) take origin, and radiate to almost every part of the cerebral cortex. The lemniscus, together with the other longitudinal strands of the tegmentum, enters its ventral part: the thalamomammillary fasciculus (bundle of Vicq d'Azyr), from the corpus mamillare, enters its anterior tubercle, while many of the fibres of the optic tract terminate in its posterior end. The thalamus also receives numerous fibres (corticothalamic) from the cells of the cerebral cortex. The fibres that arise from the cells of the thalamus form four principal groups or stalks: (a) those of the *anterior stalk* pass through

FIG. 762.—A coronal section of the brain through the intermediate mass of the third ventricle.

the frontal part of the internal capsule to the frontal lobe; (b) the fibres of the *posterior stalk* (optic radiations) arise in the pulvinar and lateral geniculate body, and are conveyed through the occipital part of the internal capsule to the occipital lobe; (c) the fibres of the *inferior stalk* leave the under and medial surfaces of the thalamus, and pass beneath the lentiform nucleus to the temporal lobe and insula; (d) those of the *parietal stalk* pass from the lateral nucleus of the thalamus to the parietal lobe. Fibres also extend from the thalamus into the caudate and lentiform nuclei of the corpus striatum—those destined for the caudate nucleus leave the lateral surface, and those for the lentiform nucleus the inferior surface, of the thalamus.

The *metathalamus* (fig. 763) comprises the geniculate bodies, which are two in number—a medial and a lateral—on either side.

The *medial geniculate body* lies under cover of the pulvinar of the thalamus and on the lateral aspect of the corpora quadrigemina. Oval in shape, with

its long axis directed forwards and lateralwards, it is lighter in colour and smaller in size than the lateral geniculate body. The inferior brachium from the inferior colliculus disappears under cover of it, while from its lateral extremity a strand of fibres passes to join the optic tract. Entering it are many acoustic fibres from the lateral lemniscus. The medial geniculate bodies are connected with one another by the commissure of Gudden, the fibres of which pass through the posterior part of the optic chiasma and form the medial parts of the optic tracts.

The *lateral geniculate body* is an oval elevation on the lateral part of the posterior end of the thalamus, and is connected with the superior colliculus by the superior brachium. It is of a dark colour, and presents a laminated arrangement consisting of alternate layers of grey and white substance. It

FIG. 768.—The hind- and mid-brains; posterolateral view.

receives numerous fibres from the optic tract, while other fibres of this tract pass over or through it into the pulvinar. Its cells are large and pigmented; their axons pass to the visual area in the occipital part of the cerebral cortex.

The superior colliculus, the pulvinar, and the lateral geniculate body receive many fibres from the optic tracts, and are termed the *lower visual centres*. Extirpation of the eyes in newly born animals entails an arrest of the development of these centres, but has no effect on the medial geniculate bodies or on the inferior colliculi. Moreover, the latter are well developed in the mole, an animal in which the superior colliculi are rudimentary.

The *epithalamus* comprises the trigonum habenulae, the pineal body, and the posterior commissure.

The *trigonum habenulae* is a small depressed triangular area situated in front of the superior colliculus and on the lateral aspect of the posterior part of the tectum thalami. It contains a group of nerve-cells termed the *ganglion habenulae*. Fibres enter it from the stalk of the pineal body, while others, forming what is termed the *habenular commissure*, pass across the middle line to the corresponding ganglion of the opposite side. Most of its fibres are, however, directed downwards and form a bundle, the *fasciculus retroflexus* of

Meynert, which passes medially to the red nucleus, and, after decussating with the corresponding fasciculus of the opposite side, ends in the interpeduncular ganglion.

The *pineal body* (fig. 760) is a small, conical, reddish-grey body which lies in the depression between the superior colliculi. It is placed beneath the splenium of the corpus callosum, but is separated from this by the tela chorioidea of the third ventricle, the lower layer of which envelops it. It measures about 8 mm. in length, and its base, directed forwards, is attached by a stalk or peduncle of white substance. The stalk divides anteriorly into two laminae, a dorsal and a ventral, which are separated from one another by the pineal recess of the third ventricle. The ventral lamina is continuous with the posterior commissure; the dorsal lamina is continuous with the habenular commissure and divides into two strands, termed the medullary striæ, which run forwards, one on either side, along the junction of the medial and upper surfaces of the thalamus to blend in front with the columns of the fornix.

Structure.—According to the careful investigations of Krabbe,* the pineal parenchyma consists of cells of three main varieties, namely (1) pineal cells, (2) glia-cells, and (3) nerve-cells. The pineal cells form the bulk of the parenchyma, and are of rounded shape with irregular nuclei poor in chromatin; at birth they exactly resemble the neuroblasts of the fetal brain. The glia-cells are relatively few in number, and give rise to a network of glia-fibres. The nerve-cells have scanty protoplasm and angular nuclei rich in chromatin; from the first year of life onward, they develop increasing numbers of out-running nerve-fibres with knobbed endings, and appear to have no connexion with the sympathetic fibres that accompany the blood-vessels. Connective tissue cells and fibrils appear in the pineal body during the first year of life, and habitually increase in quantity year by year, converting it into a pseudo-alveolar organ by the age of six or eight; the rate at which this fibrosis takes place is very variable. There is a connective tissue capsule, which is apparently free from unstriated muscle fibres in man. Calcareous concretions may be found in the pineal body at any age, and are constant after the seventeenth year, occurring mainly in the parenchyma and representing debris of the pineal cells. Spaces or cysts also occur normally in the pineal body, and may be either included portions of the embryonic pineal recess of the third ventricle and lined with ependyma, or due to degeneration of parts of the pineal parenchyma. Krabbe's researches lead him to conclude that the pineal body is neither a rudimentary nor a functionless organ, but that its various histological elements show signs of an unbalanced activity possibly due to variations in the pressure of the cerebrospinal fluid.

The human pineal body is phylogenetically homologous with the parietal eye of cyclostome fishes. Creutzfeldt has pointed out that it is best developed in ruminants and horses, but absent in elephants, seals, dasyurus, the mole, and many other animals, and he connects its presence with the possession of a relatively thin skin.

Applied Anatomy.—The function of the pineal body in the human body is very uncertain. Probably it has an internal secretion, though this is not proved. Possibly its function is to regulate the pressure of the cerebrospinal fluid. The growth of a tumour in the pineal body, itself of rare occurrence, has led in a few instances to sexual precocity or to obesity. The operative removal of the pineal body from puppies produces no abnormality in their subsequent development.

The *posterior commissure* is a rounded band of fibres crossing the middle line on the dorsal aspect of the upper end of the cerebral aqueduct. Its fibres acquire their medullary sheaths early, but their connexions have not been definitely determined. Most of them have their origin in a nucleus, the *nucleus of the posterior commissure*, which lies in the central grey substance of the upper end of the cerebral aqueduct, in front of the nucleus of the oculomotor nerve: some are probably derived from the posterior part of the thalamus and from the superior colliculus; others are believed to be continued downwards into the medial longitudinal fasciculus.

The *hypothalamus* (fig. 764) includes the subthalamie tegmental region and the structures forming the greater part of the floor of the third ventricle, viz. the corpora mamillaria, tuber cinereum, infundibulum, hypophysis, and optic chiasma.

The *subthalamie tegmental region* consists of the upward continuation of the tegmentum; it lies on the ventrolateral aspect of the thalamus and separates it from the fibres of the internal capsule. The red nucleus and the

* K. H. Krabbe, Abstract in *Review of Neurol. and Psychiatry*, Edinburgh, 1915, xiii, 300.

substantia nigra are prolonged into its lower part; in front it is continuous with the substantia innominata of Meynert, medially with the grey substance of the floor of the third ventricle. It consists from above downwards of three strata: (1) *stratum dorsale*, directly applied to the under surface of the thalamus and consisting of fine longitudinal fibres; (2) *zona incerta*, a continuation forwards of the formatio reticularis of the tegmentum; and (3) the *corpus subthalamicum* or *nucleus of Luys*, a brownish mass presenting a lenticular shape on transverse section, and situated on the dorsal aspect of the fibres of the base of the cerebral peduncle; it is encapsuled by a

FIG. 764.—A median sagittal section of the brain. The relations of the pia mater are indicated by the red colour.

lamina of nerve-fibres and contains numerous medium-sized nerve-cells the connexions of which are as yet not fully determined.

The *corpora mamillaria* are two round white masses, each about the size of a small pea, placed side by side below the grey substance of the floor of the third ventricle in front of the posterior perforated substance. They consist of white substance externally and of grey substance internally, the cells of the latter forming two nuclei, a *medial* of smaller and a *lateral* of larger cells. The white substance is mainly formed by the fibres of the columns of the fornix, which descend to the base of the brain and end partly in the corpora mamillaria. From the cells of the grey substance of each mamillary body two fasciculi arise; one, the thalamomamillary fasciculus (bundle of Vicq d'Azyr), passes upwards into the anterior nucleus of the thalamus; the other is directed downwards into the tegmentum. Afferent fibres are believed to reach the corpus mamillare from the medial lemniscus and from the tegmentum.

The *tuber cinereum* is a hollow eminence of grey substance situated between the corpora mamillaria behind, and the optic chiasma in front. Laterally it is

continuous on either side with the anterior perforated substance, and anteriorly with a thin lamina, the *lamina terminalis*. From the under surface of the tuber cinereum a hollow conical process, the *infundibulum*, projects downwards and forwards and is attached to the posterior lobe of the hypophysis.

FIG. 765.—A sagittal section of the hypophysis cerebri, in situ. (Testut.)

- 1, 1'. Anterior and posterior lobes of hypophysis. 2. Infundibulum. 3. Optic chiasma. 4. Lamina terminalis. 5. Optic recess. 6. Anterior commissure. 7, 7'. Circular sinus. 8. Anterior cerebral artery. 9. Basilar artery. 10. Posterior cerebral artery. 11. Corpus mamillare. 12. Cerebral peduncle. 13. Pons.

It is attached to the end of the infundibulum, and is situated in the fossa hypophyseos of the sphenoidal bone, where it is retained by a circular fold of dura mater, the *diaphragma sellæ*; this fold almost completely roofs in the fossa, leaving only a small central aperture through which the infundibulum passes.

In the lateral part of the tuber cinereum is a nucleus of nerve-cells, the *basal optic nucleus of Meynert*, while close to the cavity of the third ventricle are three additional nuclei.

Between the tuber cinereum and the corpora mamillaria a small elevation, with a corresponding depression in the third ventricle, is sometimes seen. Retzius has named it the *eminencia saccularis*, and regards it as a representative of the *saccus vasculosus* found in this situation in some of the lower vertebrates.

The *hypophysis* (pituitary body) (fig. 765) is a reddish-grey, somewhat oval mass, measuring about 12 mm. in its transverse, and 8 mm. in its anteroposterior diameter.

FIG. 766.—Median sagittal section through the hypophysis of an adult monkey. Semidiagrammatic. (Herring.)

The hypophysis consists of an anterior and a posterior lobe, which differ from one another in their mode of development and in their structure (fig. 766). The *anterior lobe* is the larger, and is somewhat kidney-shaped, the concavity being directed backwards and embracing the posterior lobe. It is developed from a diverticulum of the ectoderm of the primitive buccal cavity or stomodæum (p. 132), and consists of a *pars anterior* and a *pars intermedia*, separated from each other by a narrow cleft, the remnant of the pouch or diverticulum. The *pars anterior* is extremely vascular and consists of granular epithelial

Is of varying size and shape, arranged in cord-like trabeculae or alveoli and separated by large, thin-walled blood-vessels. The *pars intermedia* is a thin lamina closely applied to the body and neck of the posterior lobe; it contains few blood-vessels and consists of finely granular cells between which are small masses of colloid material. The *posterior lobe* is developed as a down-growth from the floor of the embryonic brain, and during early foetal life contains a cavity continuous with that of the third ventricle. In some animals

FIG. 767.—A scheme showing the central connexions of the optic nerves and optic tracts.

(e.g. cat) this cavity persists throughout life. Although of nervous origin the posterior lobe contains no nerve-cells or fibres. It consists of neuroglia-cells and fibres and is invaded by columns which grow into it from the *pars intermedia*; imbedded in it are scattered masses of a colloid substance histologically similar to that found in the thyroid gland. In certain of the lower vertebrates (e.g. fishes) nervous structures are present, and the lobe is of large size.

Applied Anatomy.—Prof. Schäfer has isolated from the *pars intermedia* a substance, no doubt an internal secretion, that causes constriction of the blood-vessels, rise of arterial blood-pressure, and increased secretion of urine, when injected subcutaneously. Enlargement of the hypophysis and of the cavity of the sella turcica are found in the rare disease *acromegaly*, which is characterised by gradual enlargement of the face, hands, and feet, with headache and often a peculiar type of blindness. This blindness is due to

the pressure of the enlarging hypophysis on the optic chiasma (fig. 765). The pressure causes atrophy, for the most part of the nerve-fibres coming from the nasal sides of the retina; with the result that the patient loses his two temporal fields of vision while retaining his nasal fields (bitemporal hemianopsy).

Optic chiasma.—The optic chiasma is a flattened, somewhat quadrilateral band of fibres, situated at the junction of the floor and anterior wall of the third ventricle. Most of its fibres have their origins in the retina, and reach the chiasma through the optic nerves, which are continuous with its antero-lateral angles. In the chiasma, they undergo a partial decussation (fig. 767); the fibres from the nasal half of the retina decussate and enter the optic tract of the opposite side, while the fibres from the temporal half of the retina do not undergo decussation, but pass back into the optic tract of the same side. In the posterior part of the commissure, however, is a strand of fibres, the *commissure of Gudden*, which is not derived from the optic nerves; it forms a connecting link between the medial geniculate bodies.

Optic tracts.—The optic tracts are continued backwards and lateralwards from the posterolateral angles of the optic chiasma. Each passes between the anterior perforated substance and the tuber cinereum, and, winding round the ventrolateral aspect of the cerebral peduncle, divides into a medial and a lateral root. The former comprises the fibres of Gudden's commissure and passes to the medial geniculate body. The lateral root consists mainly of afferent fibres which arise in the retina and undergo partial decussation in the optic chiasma, as described; but it also contains a few fine efferent fibres which have their origins in the brain and their terminations in the retina. When traced backwards, the afferent fibres of the lateral root are found to end in the lateral geniculate body and pulvinar of the thalamus, and in the superior colliculus; and these three structures constitute the *lower visual centres*. Fibres arise from the nerve-cells in these centres, and pass through the occipital part of the internal capsule, under the name of the *optic radiations*, to the cortex of the occipital lobe of the cerebrum, where the *higher or cortical visual centre* is situated. Some of the fibres of the optic radiations take an opposite course, arising from the cells of the occipital cortex and passing to the lower visual centres. Some fibres are detached from the optic tract, and pass through the cerebral peduncle to the nucleus of the oculomotor nerve. These may be regarded as the afferent branches for the Sphincter pupillæ and Ciliaris muscles. Other fibres have been described as reaching the cerebellum through the brachia conjunctiva; while others, again, are lost in the pons.

THE THIRD VENTRICLE

The **third ventricle** (figs. 760, 764, 768) is a median cleft between the two thalami. Behind, it communicates with the fourth ventricle through the cerebral aqueduct, and in front with the lateral ventricles through the inter-ventricular foramen. Somewhat triangular in shape with the apex directed backwards, it has a roof, a floor, an anterior and a posterior boundary, and a pair of lateral walls.

The **roof** (fig. 768) is formed by a layer of epithelium, which stretches between the upper edges of the lateral walls of the cavity and is continuous with the epithelial lining of the ventricle. It is covered by and adherent to a fold of pia mater, named the tela chorioidea of the third ventricle, from the under surface of which a pair of vascular fringed processes, the *chorioid plexuses of the third ventricle*, project downwards, one on either side of the middle line, and invaginate the epithelial roof into the ventricular cavity.

The **floor** slopes downwards and forwards and is formed mainly by the structures which constitute the hypothalamus: from before backwards these are: the optic chiasma, the infundibulum and tuber cinereum, and the corpora mammillaria. Behind the last, the floor is formed by the interpeduncular fossa and the tegmenta of the cerebral peduncles. The ventricle is prolonged downwards as a funnel-shaped recess, the *recessus infundibuli*, into the infundibulum, and to the apex of the latter the hypophysis is attached.

The **anterior boundary** is constituted below by the *lamina terminalis*, a thin layer of grey substance stretching from the upper surface of the optic chiasma

to the rostrum of the corpus callosum; above by the columns of the fornix and the anterior commissure. At the junction of the floor and anterior wall, immediately above the optic chiasma, the ventricle presents a small angular recess or diverticulum, the *optic recess*. Between the columns of the fornix, and above the anterior commissure, is a second recess termed the *vulva*. At the junction of the roof with the anterior and lateral walls of the ventricle, and situated between the thalami behind and the columns of the fornix in front, is the *interventricular foramen* (foramen of Monro) through which the third communicates with the lateral ventricles.

The *posterior boundary* is constituted by the pineal body, the posterior commissure and the cerebral aqueduct. A small recess, the *recessus pinealis*, projects into the stalk of the pineal body, whilst in front of and above the pineal body is a second recess, the *recessus suprapinealis*, consisting of a diverticulum of the epithelium which forms the ventricular roof.

FIG. 768.—A coronal section of the lateral and third ventricles. (Diagrammatic.)

Each *lateral wall* consists of an upper portion formed by the medial surface of the anterior two-thirds of the thalamus, and a lower consisting of an upward continuation of the grey substance of the ventricular floor. These two parts correspond to the alar and basal laminae respectively of the lateral wall of the fore-brain vesicle and are separated from each other by a furrow, the *sulcus of Monro*, which extends from the interventricular foramen to the cerebral aqueduct (p. 94). The lateral wall is limited above by the tænia thalami. The columns of the fornix curve downwards in front of the interventricular foramen, and then run in the lateral walls of the ventricle, where, at first, they form distinct prominences, but subsequently are lost to sight. The lateral walls are joined to each other across the cavity of the ventricle by a band of grey matter, the *massa intermedia* (p. 794).

Interpeduncular fossa (fig. 769).—This is a somewhat lozenge-shaped area of the base of the brain, limited in front by the optic chiasma, behind by the anterosuperior surface of the pons, anterolaterally by the converging optic tracts and posterolaterally by the diverging cerebral peduncles. The structures contained in it have already been described; from behind forwards they are the posterior perforated substance, corpora mamillaria, tuber cinereum, infundibulum, and hypophysis.

THE TELENCEPHALON

The **telencephalon** includes: (1) the cerebral hemispheres with their cavities, the lateral ventricles; and (2) the pars optica hypothalami and

the anterior portion of the third ventricle (already described under the dien-cephalon). As intimated in the chapter on Embryology (p. 96), each cerebral hemisphere may be divided into three fundamental parts, viz. the rhinencephalon, the corpus striatum, and the neopallium. The rhinencephalon, associated with the sense of smell, is the oldest part of the telencephalon, and

FIG. 769.—The base of the brain.

forms almost the whole of the hemisphere in some of the lower animals (e.g. fishes, amphibians, and reptiles). In man it is rudimentary, whereas the neopallium undergoes great development and forms the chief part of the hemisphere.

THE CEREBRAL HEMISPHERES

The cerebral hemispheres constitute the largest part of the brain, and, when viewed together from above, assume the form of an ovoid mass broader behind than in front, the greatest transverse diameter corresponding with a line connecting the two parietal tuberosities. The hemispheres are separated by a deep median cleft, named the *longitudinal cerebral fissure*, and each possesses a central cavity, the lateral ventricle.

The longitudinal cerebral fissure contains a sickle-shaped process of dura mater, the *falx cerebri*. In front and behind, the fissure extends from the upper to the under surfaces of the hemispheres and completely separates them, but its middle portion only separates them for about one-half of their vertical extent; for at this part they are connected across the middle line by a great central white commissure, the *corpus callosum*.

In a median sagittal section (fig. 764) the cut corpus callosum presents the appearance of a broad, arched band. Its thick posterior end, termed the *splenium*, overlaps the mid-brain, but is separated from it by the tela chorioidea of the third ventricle and the pineal body. Its anterior curved end, termed the *genu*, gradually tapers into a thinner portion, the *rostrum*, which is continued downwards and backwards in front of the anterior commissure to join the lamina terminalis. Arching backwards from immediately behind the anterior commissure to the under surface of the splenium is a second white band named the *fornix*; between this and the corpus callosum are the laminae and cavity of the septum pellucidum.

SURFACES OF THE CEREBRAL HEMISPHERES

Each hemisphere presents three surfaces: lateral, medial, and inferior.

The *lateral surface* is convex in adaptation to the concavity of the corresponding half of the vault of the cranium. The *medial surface* is flat and vertical and is separated from that of the opposite hemisphere by the longitudinal fissure and the falx cerebri. The *inferior surface* is of an irregular form, and may be divided into three areas: anterior, middle, and posterior. The anterior area, formed by the orbital surface of the frontal lobe, is concave, and rests on the roof of the orbit and nose; the middle area is convex, and consists of the under surface of the temporal lobe: it is adapted to the corresponding half of the middle cranial fossa. The posterior area is concave, directed medialwards as well as downwards, and is named the *tentorial surface*, since it rests upon the tentorium cerebelli, which intervenes between it and the upper surface of the cerebellum.

These three surfaces are separated from each other by the following borders: (a) *superomedial*, between the lateral and medial surfaces; (b) *inferolateral*, between the lateral and inferior surfaces; the anterior part of this border separates the lateral from the orbital surface, and is known as the *superciliary* border; (c) *medial occipital*, between the tentorial and medial surfaces; and (d) *medial orbital*, separating the orbital from the medial surface. The anterior end of the hemisphere is named the *frontal pole*; the posterior, the *occipital pole*; and the anterior end of the temporal lobe, the *temporal pole*. About 5 cm. in front of the occipital pole on the inferolateral border is an indentation or notch, named the *pre-occipital notch*.

The surfaces of the hemispheres are moulded into a number of irregular eminences, named *gyri* or *convolutions*, and separated by furrows termed *fissures* and *sulci*. The furrows are of two kinds, *complete* and *incomplete*. The former

FIG. 770.—The lateral surface of the left cerebral hemisphere, viewed from above.

concavity directed forwards, and an *inferior genu* with its concavity directed backwards. The central sulcus forms an angle, opening forwards, of about 70° with the median plane.

The parieto-occipital fissure.—Only a small part of this fissure is seen on the lateral surface of the hemisphere, its chief part being on the medial surface. The *lateral part* (fig. 771) is situated about 5 cm. in front of the occipital pole of the hemisphere, and measures about 1.25 cm. in length. The *medial part* (fig. 772) runs downwards and forwards as a deep cleft on the medial surface of the hemisphere, and joins the calcarine fissure below and behind the posterior end of the corpus callosum. In most cases it contains a submerged gyrus.

The calcarine fissure (fig. 772) is on the medial surface of the hemisphere. It begins near the occipital pole in two converging rami, and runs forward, at first with an upward, and then with a downward, curve; it ends in the posterior part of the gyrus hippocampi, just below the splenium of the corpus

FIG. 772.—The medial surface of the left cerebral hemisphere.

callosum; a little behind the splenium it is joined at an acute angle by the medial part of the parieto-occipital fissure. The anterior part of this fissure gives rise to the prominence of the *calcar avis* in the posterior cornu of the lateral ventricle.

The cingulate sulcus (fig. 772) is on the medial surface of the hemisphere; it begins below the anterior end of the corpus callosum and runs upwards and forwards nearly parallel to the rostrum of this body; it curves in front of the genu, is continued backwards above the corpus callosum, and finally ascends to the superomedial border of the hemisphere a short distance behind the upper end of the central sulcus. It separates the superior frontal from the cingulate gyrus.

The collateral fissure (fig. 772) is on the tentorial surface of the hemisphere, and extends from near the occipital pole to within a short distance of the temporal pole. Behind, it lies below and lateral to the calcarine fissure, from which it is separated by the lingual gyrus; in front, it is situated between the hippocampal gyrus and the anterior part of the fusiform gyrus.

The circular sulcus (*sulcus limitans insulæ*) (fig. 775) is on the lower and lateral surfaces of the hemisphere: it surrounds the insula (p. 811) and separates it from the frontal, parietal, and temporal lobes.

Lobes of the hemispheres.—By means of these fissures and sulci, assisted by certain arbitrary lines, each hemisphere is divided into the following lobes; *frontal, parietal, temporal, occipital, limbic, and the insula.*

Frontal lobe.—On the lateral surface of the hemisphere this lobe extends from the frontal pole to the central sulcus, the latter separating it from the parietal lobe. Below, it is limited by the posterior ramus of the lateral fissure, which intervenes between it and the temporal lobe. On the medial surface, it is separated from the cingulate gyrus by the cingulate sulcus; and on the inferior surface, it is bounded behind by the stem of the lateral cerebral fissure.

The *lateral surface* of the frontal lobe (fig. 771) is traversed by three sulci which divide it into four gyri: the sulci are named the precentral, and the superior and inferior frontal; the gyri are the anterior central, and the superior, middle, and inferior frontal. The *precentral sulcus* runs parallel to the central sulcus, and is usually divided into an upper and a lower part; between it and the central sulcus is the anterior central gyrus. From the precentral sulcus, the *superior and inferior frontal sulci* run forwards and downwards, and divide the remainder of the lateral surface of the lobe into three parallel gyri, named, respectively, the superior, middle, and inferior frontal gyri.

FIG. 773.—The orbital surface of the left frontal lobe.

The *anterior central gyrus* is bounded in front by the precentral sulcus, behind by the central sulcus; it extends from the superomedial border of the hemisphere to the posterior ramus of the lateral cerebral fissure.

The *superior frontal gyrus* is situated above the superior frontal sulcus and is continued on to the medial surface of the hemisphere. The portion on the lateral surface of the hemisphere is more or less completely subdivided into an upper and a lower part by the *paramedial sulcus*, which, however, is frequently interrupted by bridging gyri.

The *middle frontal gyrus*, between the superior and inferior frontal sulci, is continuous with the anterior orbital gyrus on the inferior surface of the frontal lobe; it is

frequently subdivided into two by a horizontal sulcus, the *medial frontal sulcus* of Eberstaller, which ends anteriorly in a wide bifurcation.

The *inferior frontal gyrus* lies below the inferior frontal sulcus, and is continuous with the lateral and posterior orbital gyri on the inferior surface of the frontal lobe. The anterior horizontal and ascending rami of the lateral cerebral fissure subdivide it into three parts, viz.: (1) the *orbital part*, below the anterior horizontal ramus of the fissure; (2) the *triangular part* ('cap' of Broca), between the ascending and horizontal rami; and (3) the *basilar part*, behind the anterior ascending ramus. The left inferior frontal gyrus is, as a rule, more highly developed than the right, and is named the *gyrus of Broca*, from the fact that Broca described it as the centre for articulate speech.

The *inferior or orbital surface* of the frontal lobe (fig. 773) is concave, and rests on the orbital plate of the frontal bone. It is divided by an H-shaped *orbital sulcus* into four gyri. These are named, from their position, the *medial*, *anterior*, *lateral*, and *posterior orbital gyri*. The medial orbital gyrus presents a well-marked anteroposterior sulcus, the *olfactory sulcus*, for the olfactory tract; the portion medial to this is named the *gyrus rectus*, and is continuous with the superior frontal gyrus on the medial surface.

The *medial surface* of the frontal lobe is occupied by the medial part of the superior frontal gyrus (marginal gyrus) (fig. 772). It lies between the cingulate sulcus and the superomedial margin of the hemisphere. The posterior part of this gyrus is sometimes marked off by a vertical sulcus, and is named the *paracentral lobule*; it is continuous, over the superomedial border of the hemisphere, with the anterior and posterior central gyri.

Parietal lobe.—The parietal lobe is separated from the frontal lobe by the central sulcus, but its boundaries below and behind are not so definite.

Posteriorly, it is limited by the lateral part of the parieto-occipital fissure, and by a line carried across the hemisphere from the lateral end of this fissure to the pre-occipital notch. Below, it is separated from the temporal lobe by the posterior ramus of the lateral fissure, and by a line carried backwards from it to meet the line passing downwards to the pre-occipital notch.

The *lateral surface* of the parietal lobe (fig. 771) is cleft by a well-marked furrow, the *intraparietal sulcus* of Turner, which consists of an oblique and a horizontal portion. The oblique part is named the *postcentral sulcus*, and commences below, about midway between the lower end of the central sulcus and the upturned end of the lateral fissure. It runs upwards and backwards, parallel to the central sulcus, and is sometimes divided into an *upper* and a *lower* ramus. It forms the hinder limit of the posterior central gyrus.

From about the middle of the postcentral sulcus, or from the upper end of its inferior ramus, the *horizontal portion* of the intraparietal sulcus is carried backwards and slightly upwards on the parietal lobe, and is prolonged, under the name of the *occipital ramus*, into the occipital lobe, where it divides into two parts, which form nearly a right angle with the main stem and constitute the *transverse occipital sulcus*. The part of the parietal lobe above the horizontal portion of the intraparietal sulcus is named the superior parietal lobule; the part below, the inferior parietal lobule.

The *posterior central gyrus* extends from the longitudinal fissure above to the posterior ramus of the lateral fissure below. It lies parallel with the anterior central gyrus, and is connected with it below, and sometimes also above, the central sulcus.

The *superior parietal lobule* is bounded in front by the upper part of the postcentral sulcus, but is usually connected with the posterior central gyrus above the end of the sulcus; behind it, is the lateral part of the parieto-occipital fissure, round the end of which it is joined to the occipital lobe by a curved gyrus, the *arcus parietooccipitalis*; below, it is separated from the inferior parietal lobule by the horizontal portion of the intraparietal sulcus.

The *inferior parietal lobule* lies below the horizontal portion of the intraparietal sulcus, and behind the lower part of the postcentral sulcus. It is divided from before backwards into two gyri. One, the *supramarginal*, arches over the upturned end of the lateral fissure; it is continuous in front with the postcentral gyrus, and behind with the superior temporal gyrus. The second, the *angular*, arches over the posterior end of the superior temporal sulcus, behind which it is continuous with the middle temporal gyrus.

The *medial surface* of the parietal lobe (fig. 772) is bounded behind by the medial part of the parieto-occipital fissure; in front, by the posterior end of the cingulate sulcus; and below, it is separated from the cingulate gyrus by the *subparietal sulcus*. It consists of a square-shaped convolution, termed the *præcuneus* or *quadrate lobe*.

Occipital lobe.—The occipital lobe is small and pyramidal in shape; it presents three surfaces: lateral, medial, and tentorial.

The *lateral surface* is limited in front by the lateral part of the parieto-occipital fissure, and by a line carried from the end of this fissure to the pre-occipital notch; it is traversed by the transverse occipital and the lateral occipital sulci. The *transverse occipital sulcus* is continuous with the posterior end of the occipital ramus of the intraparietal sulcus, and runs across the upper part of the lobe, a short distance behind the parieto-occipital fissure. The *lateral occipital sulcus* extends from behind forwards, and divides the lateral surface of the occipital lobe into a *superior* and an *inferior gyrus*, which are continuous in front with the parietal and temporal lobes.*

The *medial surface* of the occipital lobe is bounded in front by the medial part of the parieto-occipital fissure, and is traversed by the calcarine fissure, which subdivides it into the cuneus and the lingual gyrus. The *cuneus* is a wedge-shaped area between the calcarine fissure and the medial part of the parieto-occipital fissure. The *lingual gyrus* lies between the calcarine fissure and the posterior part of the collateral fissure; behind, it reaches the occipital pole; in front, it joins the hippocampal gyrus.

* Elliot Smith has named the lateral occipital sulcus the *sulcus lunatus*, and regards it as the representative, in the human brain, of the 'Affenspalte' of the brain of the ape.

The *tentorial surface* of the occipital lobe is limited in front by an imaginary transverse line through the pre-occipital notch, and consists of the posterior part of the *fusiform gyrus* and the lower part of the lingual gyrus, which are separated from each other by the posterior segment of the collateral fissure.

Temporal lobe.—The temporal lobe presents superior, lateral, and inferior surfaces.

The *superior surface* forms the lower limit of the lateral cerebral fissure and overlaps the *insula*. On opening out the lateral fissure, three or four gyri will be seen springing from the depth of the hinder end of the fissure, and running obliquely forwards and outwards on the posterior part of the upper surface of the superior temporal gyrus; these are named the *transverse temporal gyri* (Heschl) (fig. 774).

The *lateral surface* (fig. 771) is bounded above by the posterior ramus of the lateral fissure, and by an imaginary line continued backwards from it; below,

Fig. 774.—A section showing the upper surface of the temporal lobe.

it is limited by the inferolateral border of the hemisphere. It is divided into superior, middle, and inferior gyri by the superior and middle temporal sulci. The *superior temporal sulcus* runs from before backwards across the temporal lobe, some little distance below, but parallel with, the posterior ramus of the lateral fissure; and hence it is often termed the *parallel sulcus*. The *middle temporal sulcus* takes the same direction as the superior, but is situated at a lower level, and is usually subdivided into two or more parts. The *superior temporal gyrus* lies between the posterior ramus of the lateral cerebral fissure and the superior temporal sulcus, and is continuous behind with the supra-marginal and angular gyri. The *middle temporal gyrus* is between the superior and middle temporal sulci, and is joined posteriorly with the angular gyrus. The *inferior temporal gyrus* is placed below the middle temporal sulcus, and is connected behind with the inferior occipital gyrus; it also extends round the inferolateral border on to the inferior surface of the temporal lobe, where it is limited by the inferior temporal sulcus.

The *inferior surface* is concave, and is continuous posteriorly with the tentorial surface of the occipital lobe. It is traversed by the *inferior temporal sulcus*, which extends from near the occipital pole behind, to within a short distance of the temporal pole in front, but is frequently subdivided by bridging

Lateral to this fissure is the narrow tentorial part of the inferior temporal gyrus, and medial to it the *fusiform gyrus*, which extends from the occipital to the temporal pole; this gyrus is limited medially by the collateral fissure, which separates it from the lingual gyrus behind and from the hippocampal gyrus in front.

The *insula* (island of Reil) (fig. 775) lies deeply in the lateral cerebral fissure, and is surrounded by the circular sulcus (p. 807); it can only be seen when the lips of the lateral cerebral fissure are widely separated, since it is overlapped and hidden by the gyri which bound the fissure. These gyri are termed the *opercula of the insula*, they are separated from each other by the three rami of the lateral fissure, and are named the orbital, frontal, frontoparietal, and temporal opercula. The *orbital operculum* lies below the anterior horizontal ramus of the fissure, the *frontal* between this and the anterior ascending ramus, the *frontoparietal* between the anterior ascending ramus and

FIG. 775.—The insula of the left side, exposed by removing the opercula.

the upturned end of the posterior ramus, and the *temporal* below the posterior ramus. The frontal operculum is of small size in those cases where the anterior horizontal and ascending rami of the lateral fissure arise from a common stem. When the opercula have been removed, the insula is seen as a triangular eminence, the apex of which is directed towards the anterior perforated substance. It is divided into a larger anterior and a smaller posterior part by a deep sulcus (*sulcus centralis insulae*) which runs backwards and upwards from the apex of the insula. The anterior part is subdivided by shallow sulci into three or four *short gyri*, while the posterior part is formed by one *long gyrus*, which is often divided at its upper end. The cortical grey substance of the insula is continuous with that of the different opercula, while its deep surface corresponds with the lentiform nucleus of the corpus striatum.

Limbic lobe (fig. 772).—The term limbic lobe was introduced by Broca, and under it he included the cingulate and hippocampal gyri, which together arch round the corpus callosum and the hippocampal fissure. These he separated on the morphological ground that they are well developed in animals possessing a keen sense of smell (osmatic animals), such as the dog and fox.

The *cingulate gyrus* is an arched-shaped convolution, lying in close relation to the superficial surface of the corpus callosum, from which it is separated by a slit-like fissure, the *callosal fissure*. It commences below the rostrum of the corpus callosum, curves round in front of the genu, extends along the upper surface of the body, and finally turns downwards behind the splenium, where it is connected by a narrow *isthmus* with the hippocampal gyrus. It is

separated from the medial part of the superior frontal gyrus by the cingulate sulcus, and from the præcuneus by the subparietal sulcus.

The *hippocampal gyrus* is bounded above by the hippocampal fissure, and below by the anterior part of the collateral fissure. Behind, it is continuous superiorly, through the isthmus, with the cingulate gyrus and inferiorly with the lingual gyrus. Running in the substance of the cingulate and hippocampal gyri, and connecting them together, is a tract of arched fibres, named the *cingulum* (p. 528). The anterior extremity of the hippocampal gyrus is recurved in the form of a hook (*uncus*), which is separated from the apex of the temporal lobe by a slight fissure, the *incisura temporalis*. Although superficially continuous with the hippocampal gyrus, the uncus forms morphologically a part of the rhinencephalon.

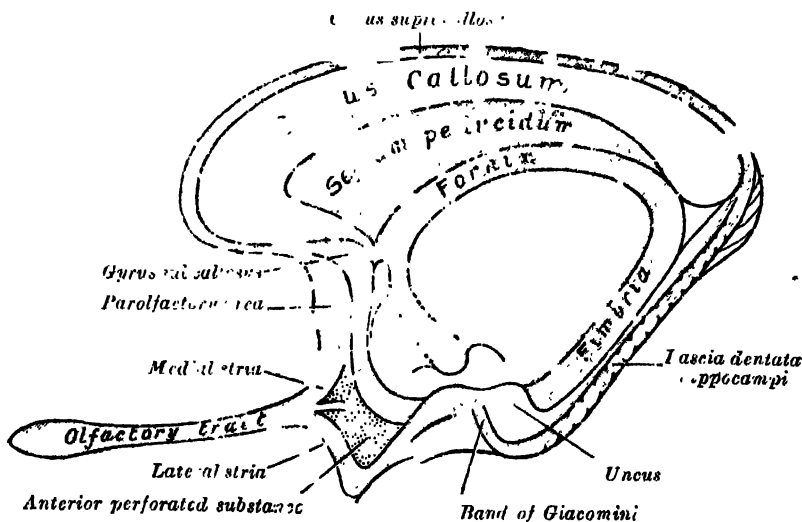

The hippocampal fissure begins immediately behind the splenium of the corpus callosum, and runs forwards between the hippocampal and dentate gyri to end in the uncus. It is a complete fissure (p. 806), and gives rise to the prominence of the hippocampus in the inferior cornu of the lateral ventricle.

RHINENCEPHALON

The *rhinencephalon* (Fig. 776) comprises the olfactory lobe, the uncus, the subcallosal and supracallosal gyri, the fascia dentata hippocampi, the septum pellucidum, the fornix and the hippocampus.

1. The *olfactory lobe* is situated under the inferior or orbital surface of the frontal lobe. It may be vibrates it as a well-marked portion

Fig. 776.—A scheme of the rhinencephalon.

of the hemisphere and contains an extension of the lateral ventricle; but in man and some other mammals it is rudimentary. It consists of the olfactory bulb and tract, the olfactory trigone, the parolfactory area of Broca, and the anterior perforated substance.

(a) The *olfactory bulb* is an oval, reddish-grey mass which lies above the lamina cribrosa of the ethmoidal bone, and forms the anterior expanded extremity of the olfactory tract. The olfactory nerves pass upwards through the lamina cribrosa from the olfactory region of the nasal cavity and enter the inferior surface of the olfactory bulb. Its minute structure is described on p. 833.

(b) The *olfactory tract* is a narrow white band, triangular on coronal section, the apex being directed upwards. It lies in the olfactory sulcus on the inferior

surface of the frontal lobe, and divides posteriorly into two striae, a medial and a lateral. The *lateral stria* is directed across the lateral part of the anterior perforated substance and then bends abruptly medialwards towards the uncus of the hippocampal gyrus. The *medial stria* turns medialwards behind the parolfactory area and ends in the subcallosal gyrus; in some cases a small *intermediate stria* is seen running backwards to the anterior perforated substance.

(c) The *olfactory trigone* is a small triangular area in front of the anterior perforated substance. Its apex, directed forwards, occupies the posterior part of the olfactory sulcus, and is brought into view by throwing back the olfactory tract.

(d) The *parolfactory area of Broca* is a small triangular field on the medial surface of the hemisphere in front of the subcallosal gyrus, from which it is separated by the posterior parolfactory sulcus; it is continuous below with the olfactory trigone, and above and in front with the cingulate gyrus; it is limited anteriorly by the *anterior parolfactory sulcus*.

(e) The *anterior perforated substance* is an irregularly quadrilateral area in front of the optic tract and behind the olfactory trigone, from which it is separated by the *fissura prima*; medially and in front it is continuous with the subcallosal gyrus; laterally it is bounded by the lateral stria of the olfactory tract and is continued into the uncus. Its grey substance is confluent above with that of the corpus striatum, and is perforated anteriorly by numerous small blood-vessels.

2. The uncus has already been described (p. 812) as the recurved, hook-like portion of the hippocampal gyrus.

3. The subcallosal, precallosal, and dentate gyri form a rudimentary arch shaped in part by grey substance extending over the corpus callosum and above the hippocampal gyrus to the anterior perforated substance to the uncus.

(a) The *subcallosal gyrus* (peduncle of the corpus callosum) is a narrow lamina on the medial surface of the hemisphere in front of the *arteria terminalis*, behind the parolfactory area, and below the posterior part of the corpus callosum. It is continuous around the genu of the corpus callosum with the supracallosal gyrus.

(b) The *supracallosal gyrus* or *callosum gyrus* consists of a thin layer of grey substance in contact with the upper surface of the corpus callosum and continuous laterally with the grey substance of the cingulate gyrus. It contains two longitudinally directed strands of white substance, the *medial* and *lateral longitudinal striae*. The supracallosal gyrus is prolonged round the splenium of the corpus callosum as a delicate band, the *fascia cuneata*, which is continuous below with the fascia dentata of the hippocampus.

(c) The *fascia dentata hippocampi* (dentate gyrus) is a narrow band extending downwards and forwards above the hippocampal gyrus but separated from it by the hippocampal fissure, its free margin is notched, and is overlapped by the fimbria—the *fimbriodentate fissure* intervening. Anteriorly it is continued into the notch of the uncus, where it bends sharply and is then prolonged as a delicate band, the *band of Giacomini*, over the uncus, on the lateral surface of which it is lost.

The remaining parts of the rhinencephalon, viz. the septum pellucidum, the fornix, and the hippocampus, will be described in connexion with the lateral ventricle.

INTERIOR OF THE CEREBRAL HEMISPHERES

If the upper part of either hemisphere be removed, at a level about 1.25 cm. above the corpus callosum, the central white substance will be exposed as an oval-shaped area, the *centrum ovale minus*, surrounded by a narrow convoluted margin of grey substance, and studded with numerous minute red dots (*puncta vasculosa*), produced by the escape of blood from divided blood-vessels. If the remaining portions of the hemispheres be drawn slightly apart a broad band of white substance, the *corpus callosum*, will be observed, connecting them at the bottom of the longitudinal fissure; the margins of the hemispheres

which overlap the corpus callosum are called the *labia cerebri*. Each labium is part of the cingulate gyrus already described; and the slit-like interval between it and the upper surface of the corpus callosum is termed the *callosal fissure* (fig. 772). If the hemisphere be sliced off until level with the upper surface of the corpus callosum, the white substance of that structure will be seen connecting the two hemispheres.* The large expanse of medullary matter now exposed, surrounded by the convoluted margin of grey substance, is called the *centrum ovale majus*.

The corpus callosum (fig. 777) is the great transverse commissure which unites the cerebral hemispheres and roofs in the lateral ventricles. A good

FIG. 777.—The corpus callosum, from above.

conception of its position and size is obtained by examining a median sagittal section of the brain (fig. 764), when it is seen to form an arched structure about 10 cm. long. Its anterior end is about 4 cm. from the frontal pole, and its posterior end about 6 cm. from the occipital pole, of the hemisphere.

The *anterior end* is named the *genu*, and is bent downwards and backwards in front of the septum pellucidum; diminishing rapidly in thickness, it is prolonged backwards, under the name of the *rostrum*, which is connected below with the lamina terminalis. The anterior cerebral arteries are in contact with the under surface of the rostrum; they then arch over the front of the genu, and are carried backwards above the body of the corpus callosum.

* A better view of the corpus callosum, and of the way in which its fibres pass into the hemisphere, is obtained by inserting the fingers into the callosal fissure and tearing off the cingulate gyrus in a lateral direction.

The *posterior end* is termed the *splenium*, and constitutes the thickest part of the corpus callosum. It overlaps the *tela chorioidea* of the third ventricle and the mesencephalon, and ends in a thick, convex, free border. A sagittal section of the splenium shows that the posterior end of the corpus callosum is acutely bent forwards, the upper and lower parts being applied to each other.

The *superior surface* is convex from before backwards, and is about 2.5 cm. wide. Its medial part forms the bottom of the longitudinal fissure, and is in contact posteriorly with the lower border of the falx cerebri. Laterally it is overlapped by the cingulate gyrus, but is separated from it by the slit-like *callosal fissure*. It is traversed by numerous transverse ridges and furrows, and is covered by a thin layer of grey matter, the *supracallosal gyrus*, which exhibits on either side of the middle line the medial and lateral longitudinal striae already described (p. 813).

FIG. 778.—A scheme showing the relations of the ventricles to the surface of the brain.

The *inferior surface* is concave, and forms on either side of the middle line the roof of the lateral ventricle. Medially, this surface is attached in front to the septum pellucidum; behind this it is fused with the upper surface of the body of the fornix, while the splenium is in contact with the *tela chorioidea*.

On either side, the fibres of the corpus callosum radiate in the white substance and pass to the various parts of the cerebral cortex; those curving forward from the genu into the frontal lobe constitute the *forceps anterior*, and those curving backwards from the splenium into the occipital lobe, the *forceps posterior*. Between these two parts is the main body of the fibres; these constitute the *tapetum* and extend laterally on either side into the temporal lobe, and cover the central part of the lateral ventricle.

The lateral ventricles (fig. 778).—The two lateral ventricles are irregular cavities situated in the lower and medial parts of the cerebral hemispheres, one on either side of the middle line. They are separated from each other by a median vertical partition, the *septum pellucidum*, but communicate with the third ventricle and indirectly with each other through the *interventricular foramen*. They are lined by a thin, diaphanous membrane, the *ependyma*.

covered by ciliated epithelium, and contain cerebrospinal fluid, which, even in health, may be secreted in considerable amount. Each lateral ventricle consists of a *central part* or *body*, and three prolongations from it, termed *cornua* (figs. 779, 780).

FIG. 779.—A drawing of a cast of the ventricular cavities, viewed from above. (Retzius.)

FIG. 780.—A drawing of a cast of the ventricular cavities, viewed from the side. (Retzius.)

The *central part* (fig. 781) of the lateral ventricle extends from the inter-ventricular foramen to the splenium of the corpus callosum. It is an irregularly curved cavity, triangular on transverse section, with a roof, a floor, and a medial wall. The roof is formed by the under surface of the corpus callosum; the floor, directed upwards and medialwards, by the following

parts, enumerated in their order of position from before backwards: the caudate nucleus of the corpus striatum, the stria terminalis and the terminal vein, the lateral portion of the upper surface of the thalamus, the choroid plexus, and the lateral part of the fornix; the medial wall is the posterior part of the septum pellucidum, which separates the ventricle from that of the opposite side.

FIG. 781.—The central parts and the anterior and posterior cornua of the lateral ventricles, exposed from above.

The anterior cornu (fig. 781) passes forwards and lateralwards, with a slight inclination downwards, from the interventricular foramen into the frontal lobe. It curves round the head of the caudate nucleus, and is bounded anteriorly by the posterior surface of the genu of the corpus callosum. In a coronal section it appears as a triangular slit below the anterior part of the corpus callosum. Its floor is convex, directed upwards and medialwards, and is formed by the head of the caudate nucleus. Its medial wall is vertical and consists of the septum pellucidum (p. 826).

The posterior cornu (figs. 781, 782) passes into the occipital lobe, its direction being backwards and lateralwards, and then medialwards. Its roof and lateral wall are formed by the fibres of the corpus callosum passing to the temporal and occipital lobes. On its medial wall is a longitudinal eminence, the *calcar avis*, which is an involution of the ventricular wall produced by the calcarine fissure. Above this the forceps posterior of the corpus callosum, sweeping round to enter the occipital lobe, causes another projection, termed the *bulb* of the posterior cornu. The calcar avis and bulb of the posterior

cornu are extremely variable in their degree of development; in some cases they are ill-defined, in others prominent.

FIG. 782.—A coronal section through the posterior cornu of the left lateral ventricle.

FIG. 783.—The posterior and inferior cornua of the left lateral ventricle, exposed from the side.

The inferior cornu (fig. 783), the largest of the three, traverses the temporal lobe, forming in its course a curve round the posterior end of the thalamus. It passes at first backwards, lateralwards, and downwards, and

then curves forwards to within 2.5 cm. of the apex of the temporal lobe, its position being fairly well indicated on the surface of the brain by the superior temporal sulcus. Its roof is formed chiefly by the inferior surface of the tapetum of the corpus callosum, but the tail of the caudate nucleus and the stria terminalis also extend forwards in the roof, at the extremity of which they end in a mass of grey substance, the *nucleus amygdalæ*. Its floor presents the following parts: the hippocampus, the fimbria hippocampi, the collateral eminence, and the chorioid plexus. When the chorioid plexus is removed, a cleft-like opening is left along the medial wall of the inferior cornu; this cleft constitutes the lower part of the chorioidal fissure.

The **hippocampus** (figs. 783, 784) is a curved eminence, about 5 cm. long, which extends throughout the entire length of the floor of the inferior cornu. Its lower end is enlarged, and presents two or three rounded elevations or digitations, which give it a paw-like appearance, and hence it is named the *pes hippocampi*. If a transverse section be made through the hippocampus, it will be seen that this eminence is produced by the folding of the wall of the hemisphere to form the hippocampal fissure. The main mass of the hippocampus consists of grey substance; but on its ventricular surface is a thin white layer, the *alveus*, which is continuous with the fimbria hippocampi.

The **collateral eminence** (fig. 784) is an elongated swelling lying lateral to and parallel with the hippocampus. It corresponds with the middle part of the collateral fissure, and its size depends on the depth and direction of this fissure. It is continuous behind with a flattened triangular area, the *trigonum collaterale*, situated between the posterior and inferior cornua.

The fimbria hippocampi is a continuation of the crus of the fornix, and will be discussed with that body; the chorioid plexus is described on p. 826.

The **corpus striatum** has received its name from the striped appearance which a section of its anterior part presents, in consequence of diverging white fibres being mixed with the grey substance which forms its chief mass. A part of the corpus striatum is imbedded in the white substance of the cerebral hemisphere, and is therefore external to the ventricle; it is termed the *extraventricular portion*, or the *lentiform nucleus*; the remainder, however, projects into the ventricle, and is named the *intraventricular portion*, or the *caudate nucleus* (fig. 785).

The **caudate nucleus** (fig. 781) is a pear-shaped, highly arched grey mass; its broad extremity, or *head*, is directed forwards into the anterior cornu of the lateral ventricle, and is continuous with the anterior perforated substance and with the anterior end of the lentiform nucleus; its narrow end, or *tail*, is directed backwards on the lateral side of the thalamus, from which it is separated by the stria terminalis and the terminal vein; it is then continued downwards into the roof of the inferior cornu, and ends in the *nucleus amygdalæ* at the apex of the temporal lobe. It is covered by the lining of the lateral ventricle, and crossed by some veins of considerable size. It is separated from the lentiform nucleus, in the greater part of its extent, by a thick lamina of white substance, called the *internal capsule*, but the two portions of the corpus striatum are united in front (figs. 786, 787).

The **lentiform nucleus** (lenticular nucleus) is lateral to the caudate nucleus and thalamus, and is seen only in sections of the hemisphere. When divided horizontally, it exhibits, to some extent, the appearance of a biconvex lens

FIG. 784.—The inferior and posterior cornua of the left lateral ventricle, viewed from above.

(fig. 785), while a coronal section of its central part presents a somewhat triangular outline. It is shorter than the caudate nucleus and does not extend as far forwards. It is bounded laterally by a lamina of white substance called the *external capsule*, and lateral to this is a thin layer of grey substance termed the *claustrum*. Its anterior end is continuous with the lower part of the head of the caudate nucleus and with the anterior perforated substance.

In a coronal section through the middle of the lentiform nucleus, two *medullary laminae* are seen dividing it into three parts. The lateral and largest

FIG. 785.—A horizontal section of the right cerebral hemisphere.

part is of a reddish colour, and is known as the *putamen*, while the medial and intermediate parts are of a yellowish tint, and together constitute the *globus pallidus*; all three are marked by fine radiating white fibres, which are most distinct in the putamen (fig. 787).

The grey substance of the corpus striatum is traversed by nerve-fibres, some of which originate in it. The cells are multipolar, both large and small; those of the lentiform nucleus contain yellow pigment. The caudate and lentiform nuclei are not only directly continuous with each other anteriorly, but are connected to each other by numerous fibres. The corpus striatum is also connected: (1) to the cerebral cortex, by the *corticostriate* fibres; (2) to the thalamus, by fibres which pass through the internal capsule, and by a strand named the *ansa lentiformis*; (3) to the cerebral peduncle, by fibres which leave the lower parts of the caudate and lentiform nuclei.

The **claustrum** (figs. 785, 787) is a thin layer of grey substance, situated on the lateral surface of the external capsule. In a coronal section it is seen to be triangular in shape, with the apex directed upwards. Its medial surface, contiguous to the external capsule, is smooth, but its lateral surface presents ridges and furrows corresponding with the gyri and sulci of the insula, with which it is in close relationship. The claustrum is regarded as a detached portion of the grey substance of the insula, from which it is separated by a layer of white fibres, the *capsula extrema* or *band of Baillarger*. Its cells are small and spindle-shaped and contain yellow pigment; they are similar to those of the deepest layer of the cortex.

FIG. 786.—A coronal section through the anterior cornua of the lateral ventricles.

The **nucleus amygdalæ** is an ovoid grey mass, situated at the lower end of the roof of the inferior cornu. It is merely a localised thickening of the grey cortex, continuous with that of the uncus; in front it is continuous with the putamen, behind with the stria terminalis and the tail of the caudate nucleus.

The **internal capsule** (fig. 788) is a flattened band of white fibres, between the lentiform nucleus on the lateral side and the caudate nucleus and thalamus on the medial side. In horizontal section (fig. 785), it is seen to be somewhat abruptly curved, with its convexity directed medialwards; the prominence of the curve is called the *genu*, and projects between the caudate nucleus and the thalamus. The portion in front of the genu is termed the *frontal part*, and separates the lentiform from the caudate nucleus; the portion behind the genu is the *occipital part*, and separates the lentiform nucleus from the thalamus.

The *frontal part* of the internal capsule contains: (1) fibres running from the thalamus to the frontal lobe; (2) fibres joining the lentiform and caudate nuclei; (3) fibres connecting the cortex with the corpus striatum; and (4) fibres

passing from the frontal lobe through the medial fifth of the base of the cerebral peduncle to the nuclei pontis. The fibres in the region of the genu are named the *geniculate fibres*; they originate in the motor part of the cerebral cortex, and, after passing downwards through the base of the cerebral peduncle with the cerebrospinal fibres, undergo decussation and end in the motor nuclei of the cerebral nerves of the opposite side. The anterior two-thirds of the occipital part of the internal capsule contains the *cerebrospinal fibres*, which arise in the motor area of the cerebral cortex, and passing downwards through the middle three-fifths of the base of the cerebral peduncle, are continued into

FIG. 787.—A coronal section of the brain through the anterior commissure.

the pyramids of the medulla oblongata. The posterior third of the occipital part contains: (1) sensory fibres, largely derived from the thalamus, though some may be continued upwards from the medial lemniscus; (2) the fibres of the optic radiation, from the lower visual centres to the cortex of the occipital lobe; (3) acoustic fibres, from the lateral lemniscus to the temporal lobe; and (4) fibres which pass from the occipital and temporal lobes to the nuclei pontis.

The fibres of the internal capsule radiate widely as they pass to and from the various parts of the cerebral cortex, forming the *corona radiata* (fig. 785) and intermingling with the fibres of the corpus callosum.

The *external capsule* (fig. 785) is a lamina of white substance, situated laterally to the lentiform nucleus, between it and the claustrum, and continuous with the internal capsule below and behind the lentiform nucleus. It probably contains fibres derived from the thalamus, the anterior commissure, and the subthalamic region.

The *substantia innominata* of Meynert is a stratum consisting of grey and white substance, which lies below the anterior part of the thalamus and

FIG. 788.—A dissection showing the course of the cerebrospinal fibres.
(E. B. Jamieson.)

but their central parts are joined together in the middle line. The anterior parts are called the columns of the fornix; the intermediate united portions, the body; and the posterior parts, the crura.

The *body* of the fornix is triangular, narrow in front, and broad behind. The medial part of its upper surface is connected to the septum pellucidum in front and to the corpus callosum behind. The lateral portion of this surface forms part of the floor of the lateral ventricle, and is covered by the ventricular epithelium. Its thin lateral edge overlaps the chorioid plexus, and is continuous with the epithelial covering of this structure. The under surface

FIG. 789.—The fornix and the corpus callosum, from below. (From a specimen in the Department of Human Anatomy of the University of Oxford.)

rests upon the tela chorioidea of the third ventricle or velum interpositum, which separates it from the epithelial roof of the third ventricle, and from the medial portions of the upper surfaces of the thalami. The lateral portions of the body of the fornix are joined inferiorly by a thin triangular lamina, named the *psalterium* or *lyra*. This lamina contains some transverse fibres which connect the two hippocampi across the middle line and constitute the *hippocampal commissure*. Between the psalterium and the corpus callosum a horizontal cleft, the so-called *ventricle of the fornix* or *ventricle of Verga*, is sometimes found.

The *columns* (anterior pillars) of the fornix arch downwards in front of the thalamus and behind the anterior commissure, and form the anterior boundary of the interventricular foramen; each descends through the grey substance in the lateral wall of the third ventricle to the base of the brain, where it ends in the corpus mamillare. From the cells of the corpus mamillare

the *thalamomamillary fasciculus* (bundle of Vieq d'Azyr) takes origin and is prolonged into the anterior nucleus of the thalamus. The column of the fornix and the thalamomamillary fasciculus together form a loop resembling the figure 8, but the continuity of the loop is broken in the corpus mamillare. The column of the fornix is joined by the stria medullaris of the pineal body and by the superficial fibres of the stria terminalis; it is said also to receive fibres from the septum pellucidum. Zuckerkandl describes an *olfactory fasciculus* which becomes detached from the main portion of the column of the fornix, and passes downwards in front of the anterior commissure to the base of the brain, where it divides into two bundles: one joins the medial stria of the olfactory tract; the other joins the subcallosal gyrus, and through it reaches the hippocampal gyrus.

The *crura* (posterior pillars) of the fornix are prolonged backwards from the body. They are flattened bands, and at their commencement are intimately connected with the under surface of the corpus callosum. Diverging from

FIG. 790.—A coronal section of the inferior cornu of the lateral ventricle. (Diagrammatic.)

one another, each curves round the posterior end of the thalamus, and passes downwards and forwards into the inferior cornu of the lateral ventricle. (figs. 784, 789). Here it lies along the concavity of the hippocampus, on the surface of which some of its fibres are spread out to form the *alveus*, while the remainder are continued as a narrow white band, the *fimbria hippocampi*, which is prolonged into the uncus of the hippocampal gyrus. The inner edge of the fimbria overlaps the fascia dentata hippocampi (dentate gyrus) (p. 813), from which it is separated by the *fimbriodentate fissure*; from its lateral, thin edge the ventricular epithelium is reflected over the chorioid plexus as the latter projects into the chorioidal fissure.

Interventricular foramen (foramen of Monroe).—Between the columns of the fornix and the anterior ends of the thalami, an oval aperture is present on either side: this is the interventricular foramen, and through it the lateral ventricles communicate with the third ventricle. Behind the epithelial lining of the foramen the chorioid plexuses of the lateral ventricles are joined across the middle line.

The anterior commissure is a bundle of white fibres, connecting the two cerebral hemispheres across the middle line, and placed in front of the columns of the fornix. On sagittal section it is oval in shape, its long diameter being vertical and measuring about 5 mm. Its fibres can be traced lateralwards and backwards on either side beneath the corpus striatum into the substance of the temporal lobe. It connects the two temporal lobes, and also contains decussating fibres from the olfactory tracts.

The *septum pellucidum* (fig. 764) is a thin, vertically placed partition consisting of two laminae, separated in the greater part of their extent by a narrow chink or interval, the *cavity of the septum pellucidum*. It is attached, above, to the under surface of the corpus callosum; below, to the anterior part of the fornix behind, and the reflected portion of the corpus callosum in front. It is triangular in form, with its base in front; its inferior angle corresponds with the upper part of the anterior commissure. The lateral surface of each lamina is directed towards the body and anterior cornu of the lateral ventricle, and is covered by the ependyma of that cavity.

FIG. 791.—The tela chorioidea of the third ventricle, and the chorioid plexus of the left lateral ventricle, exposed from above.

The *cavity of the septum pellucidum* is generally regarded as part of the longitudinal cerebral fissure, which has become shut off by the union of the hemispheres in the formation of the corpus callosum above and the fornix below. Each half of the septum therefore forms part of the medial wall of the hemisphere, and consists of a medial layer of grey substance derived from that of the cortex, and a lateral layer of white substance continuous with that of the cerebral hemispheres. This cavity is not developed from the cavity of the cerebral vesicles, and never communicates with the ventricles of the brain.

The chorioid plexus of the lateral ventricle (fig. 791) is a highly vascular, fringe-like process of pia mater, which projects into the ventricular cavity. The plexus, however, is everywhere covered by a layer of epithelium continuous with the epithelial lining of the ventricle. It extends from the interventricular foramen, where it is joined with the plexus of the opposite

ventricle, to the end of the inferior cornu. The part in relation to the body of the ventricle forms the vascular fringed margin of a triangular process of pia mater, named the tela chorioidea of the third ventricle, and projects from under cover of the lateral edge of the fornix. It lies upon the upper surface of the thalamus, from which the ventricular epithelium is reflected over the plexus on to the edge of the fornix (fig. 768). The portion in relation to the inferior cornu lies in the concavity of the hippocampus and overlaps the fimbria hippocampi; from the lateral edge of the fimbria the epithelium is reflected over the plexus on to the roof of the cornu (fig. 790).

The chorioid plexus consists of minute and highly vascular villous processes, each with an afferent and an efferent vessel. The *arteries* of the plexus are: (a) the anterior chorioid, a branch of the internal carotid artery, which enters the plexus at the end of the inferior cornu; and (b) the posterior chorioid, one or two small branches of the posterior cerebral artery, which pass forwards under the splenium. The *veins* of the plexus unite to form a tortuous vein, which courses from behind forwards to the interventricular foramen and there joins with the terminal vein (p. 680) to form the corresponding internal cerebral vein.

When the chorioid plexus is pulled away, the continuity between its epithelial covering and the epithelial lining of the ventricle is severed, and a cleft-like space is produced. This is named the *chorioid fissure*; like the plexus, it extends from the interventricular foramen to the end of the inferior cornu. The upper part of the fissure, i.e. the part nearest the interventricular foramen, is situated between the lateral edge of the fornix and the upper surface of the thalamus; farther back, at the beginning of the inferior cornu, it is between the commencement of the fimbria hippocampi and the posterior end of the thalamus, while in the inferior cornu it lies between the fimbria in the floor and the stria terminalis in the roof of the cornu.

The tela chorioidea of the third ventricle (*velum interpositum*) (fig. 791) is a double fold of pia mater, triangular in shape, which lies beneath the fornix. The lateral portions of its lower surface rest upon the thalami, while the medial portion of this surface is in contact with the epithelial roof of the third ventricle. Its apex is situated at the interventricular foramen; its base corresponds with the splenium of the corpus callosum, and occupies the interval between that structure above and the corpora quadrigemina and pineal body below. This interval, together with the lower portions of the chorioid fissures, is sometimes spoken of as the *transverse fissure* of the brain. The two layers of the tela separate from each other at the base, and are continuous with the pia mater investing the brain in this region. Its lateral margins are modified to form the highly vascular chorioid plexuses of the lateral ventricles. It is supplied by the anterior and posterior chorioid arteries already described. The veins of the tela chorioidea are named the internal cerebral veins (*venæ Galeni*); they are two in number, and run backwards between its layers, each being formed at the interventricular foramen by the union of the terminal vein with the chorioid vein. The internal cerebral veins unite posteriorly in a single trunk, the great cerebral vein (*vena magna Galeni*), which curves backwards and upwards behind the splenium of the corpus callosum and ends in the straight sinus.

STRUCTURE OF THE CEREBRAL HEMISPHERES

The cerebral hemispheres are composed of grey and white substance: the former covers their surfaces, and is termed the *cortex*; the latter occupies the interior of the hemispheres.

The white substance consists of medullated fibres, varying in size, and arranged in bundles supported by neuroglia. The fibres may be divided, according to their course and connexions, into three systems. 1. Projection fibres connect the hemisphere with the lower parts of the brain and with the medulla spinalis. 2. Transverse or commissural fibres unite the two hemispheres. 3. Association fibres connect different structures in the same hemisphere; these are, in many instances, collateral branches of the projection fibres, but others are the axons of independent cells.

1. The **projection fibres** consist of efferent and afferent fibres uniting the cortex with the lower parts of the brain and with the medulla spinalis. The principal efferent strands are : (1) the motor tract, occupying the genu and anterior two-thirds of the occipital part of the internal capsule, and consisting of (a) the geniculate fibres, which decussate and end in the motor nuclei of the cerebral nerves of the opposite side ; and (b) the cerebrospinal fibres, which are prolonged through the pyramid of the medulla oblongata into the medulla spinalis ; (2) the corticopontine fibres, ending in the nuclei pontis. The chief afferent fibres are : (1) those of the brachia conjunctiva cerebelli which are not interrupted in the red nucleus and thalamus ; (2) numerous fibres arising within the thalamus, and passing through its stalks to the different parts of the cortex (p. 796) ; (3) optic and acoustic fibres, the former passing to the occipital, the latter to the temporal lobe.

FIG. 792.—A diagram showing the principal systems of association fibres in the cerebrum.

2. The **transverse or commissural fibres** connect the two hemispheres. They include : (a) the transverse fibres of the corpus callosum, (b) the anterior commissure, (c) the posterior commissure, and (d) the lyra or hippocampal commissure ; they have already been described.

3. The **association fibres** (fig. 792) unite different parts of the same hemisphere, and are of two kinds : (1) *short association fibres* connecting adjacent gyri ; (2) *long association fibres* passing between more distant parts.

The *short association fibres* lie immediately beneath the grey substance of the cortex of the hemispheres, and connect adjacent gyri.

The *long association fibres* include the following : (a) the uncinat fasciculus ; (b) the cingulum ; (c) the superior longitudinal fasciculus ; (d) the inferior longitudinal fasciculus ; (e) the perpendicular fasciculus ; (f) the occipito-frontal fasciculus ; and (g) the fornix.

(a) The *uncinate fasciculus* passes across the bottom of the lateral cerebral fissure, and unites the gyri of the frontal lobe with the anterior end of the temporal lobe.

(b) The *cingulum* is contained within the cingulate gyrus. Beginning in front at the anterior perforated substance, it passes forwards and upwards parallel with the rostrum, winds round the genu, runs backwards above the body of the corpus callosum, turns round the splenium, and ends in the hippocampal gyrus.

(c) The *superior longitudinal fasciculus* passes backwards from the frontal lobe above the lentiform nucleus and insula ; some of its fibres end in the

occipital lobe, and others curve downwards and forwards into the temporal lobe.

(d) The *inferior longitudinal fasciculus* connects the temporal and occipital lobes, running along the lateral walls of the inferior and posterior cornua of the lateral ventricle.

(e) The *perpendicular fasciculus* runs vertically through the front part of the occipital lobe, and connects the inferior parietal lobule with the fusiform gyrus.

(f) The *occipitofrontal fasciculus* passes backwards from the frontal lobe, along the lateral border of the caudate nucleus, and on the medial aspect of the corona radiata; its fibres radiate in a fan-like manner and pass into the occipital and temporal lobes laterally to the posterior and inferior cornua. Dejerine regards the fibres of the tapetum as being derived from this fasciculus, and not from the corpus callosum.

(g) The *fornix* connects the hippocampal gyrus with the corpus mamillare, and, by means of the thalamomamillary fasciculus, with the thalamus (p. 825). Through the fibres of the hippocampal commissure it probably also unites the right and left hippocampal gyri.

The grey substance of the hemisphere is divided into: (1) that of the cerebral cortex, and (2) that of the caudate nucleus, the lentiform nucleus, the claustrum, and the nucleus amygdalæ.

STRUCTURE OF THE CEREBRAL CORTEX (fig. 793)

The cerebral cortex differs in thickness and structure in different parts of the hemisphere. It is thinner in the occipital region than in the anterior and posterior central gyri, and it is also much thinner at the bottom of the sulci than on the top of the gyri.

The cortex is made up of nerve-cells of varying size and shape, and of nerve-fibres which are either medullated or naked axis-cylinders, imbedded in a matrix of neuroglia. According to J. S. Bolton, it exhibits five layers:

1. The outer fibre-lamina (molecular or plexiform layer).
2. The outer cell-lamina.
3. The middle cell-lamina (layer of granules).
4. The inner fibre-lamina (inner band of Baillarger).
5. The inner cell-lamina (polymorphous layer).

1. The *outer fibre-lamina*.—The superficial part of this layer consists of a stratum of medullated nerve-fibres (plexus of Exner), running parallel with the surface. The deeper part is largely composed of the dendrites of cells from the subjacent laminae. It contains also a few nerve-cells, and the terminations of fibres which run into the cortex from the white substance of the hemisphere. The cells are of two kinds: (1) small irregular cells with a varying number of dendrites and short axons; (2) fusiform cells with their long axes parallel with the surface; the dendrites and the axons of the latter run horizontally, and the axons give off numerous collaterals. The distribution of the axons of both types of cell is limited to the outer fibre-lamina.

2. The *outer cell-lamina* contains a large number of pyramidal nerve-cells which are small (10μ to 15μ in length) in the superficial part, but large (20μ to 30μ) in the deep part of the lamina. Each pyramidal cell contains granular pigment and a large round or oval nucleus, and the apex of the cell is directed towards the surface. The axon arises from the base of the cell, and runs into the central white substance, giving off collaterals in its course, and being distributed as a projection, association, or commissural fibre. The apical and basal parts of the cell give off dendrites; the apical dendrite ends in the molecular layer by dividing into numerous branches, all of which may be seen, when stained by the silver or methylene blue method, to be studded with bristle-like processes.

3. The *middle cell-lamina* or layer of granules consists chiefly of small stellate cells, but some pyramidal cells are also present in its deepest part. The axons of the stellate cells run a short course, and terminate either in the same layer or in the outer cell-lamina. The axons of some of the pyramidal cells descend for a short distance and then turn back and end in the outer

cell-lamina; the axons of others run into the central white substance. In this lamina a well-marked stratum of nerve-fibres (*external band of Baillarger*) runs parallel with the cortex.

The middle cell-lamina is especially developed in the occipital lobe (visuo-sensory area), where it consists of two layers which are separated by the layer of white nerve-fibres, which is here named the *band of Gennari*.

FIG. 798.—A diagram to show the layers of cells and fibres in the grey substance of the cortex of the human cerebral hemisphere, according to the histological methods of Golgi, Nissl and Weigert. From Luciani's Physiology (Macmillan & Co., Ltd.).

4. The inner fibre-lamina is composed of medullated nerve-fibres running parallel with the surface, and forming the *internal band of Baillarger*. In the anterior central gyrus and in the paracentral lobule it contains large pyramidal cells, the *giant-cells of Betz*, which are often solitary, but may occur in groups of three to five. These cells may be 50μ in length and 40μ in breadth; in the paracentral lobule they may attain a length of 65μ .

5. The inner cell-lamina or polymorphous layer contains cells of various

shapes—fusiform, oval, triangular, or stellate. Their dendrites are directed outwards, but do not reach the molecular layer; most of their axons pass into the subjacent white substance. The axons of a few of these cells (cells of Golgi's second type) are short, and terminate in the adjacent grey substance. The cells of *Martinotti* in the inner cell-lamina are pyramidal in shape with their bases directed towards the surface; their dendrites are short, and their axons pass out into the outer fibre-lamina, where they form an extensive horizontal arborisation.

In addition to the bands of medullated fibres described above as running parallel with the surface (*tangential fibres*), two other tangential bands occur, the *band of Bechterew* in the outer cell-lamina, and the deep tangential fibres in the lower part of the inner cell-lamina. The tangential fibres consist of (a) the collaterals of the axons of the pyramidal and polymorphous cells, and of the cells of *Martinotti*; (b) the branching axons of Golgi's cells; (c) the collaterals and terminal arborisations of the projection, commissural, and association fibres. *Radial fibres* also occur in the cortex and are, on the one hand, the axons of the pyramidal and polymorphous cells descending into the white substance, and, on the other, the terminations of projection, commissural, or association fibres, ascending to end in the cortex. The axons of the cells of *Martinotti* are also ascending fibres.

Development of the laminae of the cortex.—The inner cell-lamina is the first to appear in the course of development, and in the sixth month of foetal life it has attained three-fourths of its adult depth. The inner fibre-lamina is associated with the inner cell-lamina, and although it does not appear until the sixth month of foetal life, it reaches its adult depth very quickly. The middle cell-lamina can be distinguished in the sixth month of foetal life; at this period it is one-half, and at birth three-fourths of the depth which it finally attains. The outer cell-lamina is the last to develop, both ontogenetically and phylogenetically, and its depth varies with the intellectual capacity of the individual. The outer fibre-lamina is well developed at birth, and its further growth is associated with that of the outer cell-lamina.

SPECIAL TYPES OF CEREBRAL CORTEX

The histological investigations of Bevan Lewis, Bolton, Campbell, and Brodmann, the embryological researches of Flechsig, and the experimental work of Sherrington and many others, have shown that the cortex of the cerebral hemispheres can be mapped out into areas which possess different functions, and that the minute structure of the cortex varies characteristically in these different areas. The anterior central gyrus (motor area), the convolutions bounding the calcarine fissure (visuosensory area), the prefrontal district (associational area), and the hippocampal gyrus may be taken as types.

The **motor area** (figs. 794, 795) is characterised by the presence of the giant-cells of Betz in the inner fibre-lamina, and by the absence or very slight development of the middle cell-lamina. Physiological investigations show that the centres for the lower limb are located on the highest part of the anterior central gyrus and its continuation on to the paracentral lobule; those for the trunk are on the upper portion, and those for the upper limb on the middle portion of the anterior central gyrus. The facial centres are situated on the lower part of the same gyrus, those for the tongue, larynx, muscles of mastication, and pharynx on the frontal operculum, while those for the head and neck occupy the posterior end of the middle frontal gyrus.

The **visuosensory area** (figs. 794, 795) is distinguished by the presence of the band of Gennari superficial to the middle cell-lamina and a second layer of granules between the band of Gennari and the outer cell-lamina. When blindness exists, the band of Gennari and the layers of granules superficial to it are diminished in depth, the former by as much as 50 per cent. in old-standing cases of optic atrophy. During development the visuosensory area matures rapidly; its outer cell-lamina develops early, but in the adult is only five-ninths of the depth of the same layer in the prefrontal region.

The visuosensory area is surrounded by a zone 1 cm. or more in breadth, known as the **visuopsychic area**. In this zone the outer superadded layer of granules suddenly ceases, and the outer cell-lamina is more developed. In infants one

FIG. 794.—The areas of localisation on the lateral surface of the left cerebral hemisphere

Motor area in red. Area of general sensations in blue. Auditory area in green. Visual area in yellow. The psychic portions are in lighter tints.

FIG. 795.—The areas of localisation on the medial surface of the left cerebral hemisphere.

Motor area in red. Area of general sensations in blue. Visual area in yellow. Olfactory area in purple. The psychic portions are in lighter tints.

month old the outer cell-lamina is two-thirds, and at the age of three months it is three-fourths, of the adult depth. The structure of the visuopsychic area is not modified by blindness.

The minute structure of the other sensory areas of the cortex resembles that of the visual area. These other sensory areas are as follows: the **auditory area** occupies the middle third of the superior temporal gyrus and

the adjacent gyri in the lateral cerebral fissure; the auditopsychic area is a zone surrounding the auditosensory area and has not been exactly defined; the area for the *sense of taste* is probably in the uncus and hippocampal gyrus; that for the *sense of smell* is the rhinencephalon; the area for *heat, cold, and pain* is somewhat diffuse, but the areas for the *tactile* and *muscular senses* are located mainly in the posterior central gyrus (fig. 794).

The associational areas are three in number: (1) the prefrontal, (2) an area occupying the posterior portions of the temporal and parietal lobes, and (3) the insula. The prefrontal associational area is especially characteristic of the human brain, and it may be taken as the type. It is distinguished by the great development of the outer cell-lamina; the cells of this lamina are undifferentiated in the sixth month of foetal life, and the lamina is only one-fourth of the adult depth; it is the only layer which varies appreciably in depth in normal brains, and it is under-developed in idiots and imbeciles; it is the last to be evolved and the first to retrogress (Bolton). A special

FIG. 796.—A coronal section of the olfactory bulb. (Schwalbe.)

feature of the insula is the detachment of the polymorphous layer which is known as the claustrum (p. 821); the capsula extrema is a greatly thickened inner line of Baillarger.

The minute structure of the hippocampus, the fascia dentata, and the olfactory bulb calls for special description.

In the hippocampus the white substance is represented by a layer termed the *alveus* which lies next the ventricular ependyma. The grey substance consists of: (1) a layer of large pyramidal cells next the alveus; (2) a layer occupied by the apical dendrons of the pyramidal cells, and called the *stratum radiatum*; (3) a molecular layer, the deeper part of which, called the *stratum lacunosum*, exhibits interlacing fibres and dendrites, and contains numerous small, angular nerve-cells; near the dentate gyrus there is a layer of small cells, internal to the stratum lacunosum, known as the *stratum granulosum*.

In the fascia dentata hippocampi (dentate gyrus) the molecular layer contains some pyramidal cells, while the layer of pyramidal cells is almost entirely represented by small ovoid cells.

The olfactory bulb.—In many animals the olfactory bulb contains a cavity which communicates through the olfactory tract with the lateral ventricle. In man the original cavity is filled by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of grey and white substance, but this is scanty and ill-defined. A section through the ventral part (fig. 796) shows it to consist of the following layers from without inwards: (1) A layer of olfactory nerve-fibres;

these fibres are the non-medullated axons prolonged from the olfactory cells of the nasal cavity, and reach the bulb by passing through the lamina cribrosa of the ethmoidal bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrites of the mitral cells, presently to be described. (2) Glomerular layer.—This contains numerous spheroidal bodies, termed *glomeruli*, each of which is produced by the branching and interlacement of the terminations of one or more olfactory nerve-fibres with the descending dendrite of a mitral cell. (3) Molecular layer.—This is formed of a matrix of neuroglia, imbedded in which are the *mitral cells*. These cells are pyramidal in shape, and the basal part of each gives off a thick dendrite which descends into one of the glomeruli, where it ends as indicated above, and others which interlace with similar dendrites of neighbouring mitral cells. The axons of the mitral cells pass into the next layer, and, bending backwards, are continued into the olfactory tract. (4) Nerve-fibre layer.—This lies next the central core of neuroglia, and its fibres consist of the axons of the mitral cells passing to the brain; some efferent fibres are, however, also present, and end in the molecular layer, but nothing is known as to their exact origin.

Weight of the brain.—The average weight of the brain, in the adult male, is about 1380 gms.; that of the female, about 1250 gms. In the male, the maximum weight out of 278 cases was 1840 gms. and the minimum weight 964 gms. The maximum weight of the adult female brain, out of 191 cases, was 1585 gms. and the minimum weight 879 gms. The brain increases rapidly during the first four years of life, and reaches its maximum weight by about the twentieth year. As age advances, the brain decreases slowly in weight; in old age the decrease takes place more rapidly, and may amount to about 28 gms.

The human brain is heavier than that of any of the lower animals, except the elephant and whale. The brain of the elephant weighs from 3500 to 4500 gms., and that of a whale, in a specimen 22·8 metres long, weighed rather more than 2250 gms.

Applied Anatomy.—The *internal capsule* is of great interest to the clinician because it is so often the seat of hæmorrhage from the lenticulo-striate and lenticulo-optic arteries (Charcot's 'arteries of cerebral hæmorrhage'), or of thrombosis, in patients whose vessels are weakened by old age or disease. A 'stroke,' or 'apoplexy,' is the result; blood is effused from the ruptured vessel and tears up the surrounding brain tissue, and also interferes with the neighbouring fibres by the compression set up by its mass. If the hæmorrhage is sudden and at all large, rapid and complete loss of consciousness follows, with paralysis of the opposite side of the body and loss of control over the sphincters. If it is the occipital part of the internal capsule that is involved, the paralysis will be more marked in the leg than in the arm, and will be associated with hemianæsthesia, and also with homonymous hemianopsia or blindness of the corresponding halves of the two retinæ, the patient being unable to see objects on the opposite side of the body. If the hæmorrhage is very extensive blood often makes its way into the ventricles, and death may follow in a few hours or days without recovery of consciousness, and with hyperpyrexia. If the hæmorrhage is small, consciousness is soon regained, and a fair degree of recovery from the paralysis follows, particularly in the leg. If the hæmorrhage takes place very slowly, the hemiplegia sets in gradually (ingravescent apoplexy), with headache and gradual clouding of the faculties. It is the upper motor neuron (see p. 836) that is injured in cerebral hæmorrhage; hence the muscles on the affected side of the body become spastic, with increased reflexes, while such muscular atrophy as follows is mainly due to disuse. The cerebral arteries are liable to sudden obstruction by embolism in persons with heart disease, and by thrombosis in those with diseased arteries. The effects of either embolism or thrombosis here are comparable with those of cerebral hæmorrhage, though the resulting hemiplegia or paralysis is often more gradual in its onset, and less severe in its general results.

MOTOR AND SENSORY TRACTS

The anatomy of the various parts of the central nervous system having been described, a short account will now be given of the chief motor and sensory nerve-tracts connecting the brain and the medulla spinalis. The methods employed in elucidating this complex subject have already been referred to (p. 754).

MOTOR TRACT (fig. 797)

The constituent fibres of this tract are the axis-cylinder processes of cells situated in the motor area of the cortex. The fibres converge as they descend through the corona radiata, and pass between the lentiform nucleus and

FIG. 797.—The motor tract. (Modified from Poirier.)

thalamus, in the genu and anterior two-thirds of the occipital part of the internal capsule; those in the genu are named the geniculate fibres, while the remainder constitute the cerebrospinal fibres; proceeding downwards, they enter the middle three-fifths of the base of the cerebral peduncle. The geniculate fibres cross the middle line, and end by arborising around the cells of the motor nuclei of the cerebral nerves. The cerebrospinal fibres are continued

downwards into the pyramids of the medulla oblongata, and the transit of the fibres from the medulla oblongata is effected by two paths. The fibres nearest to the anterior median fissure cross the middle line, forming the *decussation of the pyramids*, and descend in the opposite lateral funiculus of the medulla spinalis, as the lateral cerebrospinal fasciculus (crossed pyramidal tract). Throughout the length of the medulla spinalis fibres from this column pass into the grey substance, to terminate by ramifying around cells of the posterior column, the axons of which in turn make contact with the motor cells of the anterior column. The more laterally placed cerebrospinal fibres do not decussate in the medulla oblongata, but descend as the anterior cerebrospinal fasciculus (direct pyramidal tract); these fibres, however, end in the grey column of the opposite side of the medulla spinalis after crossing in the anterior white commissure. There is considerable variation in the extent to which decussation takes place in the medulla oblongata; about two-thirds or three-fourths of the fibres usually decussate in the medulla oblongata and the remainder in the medulla spinalis.

The axons of the motor cells in the anterior column pass out as the fibres of the anterior roots of the spinal nerves, along which the impulses are conducted to the muscles of the trunk and limbs.

From this it will be seen that, generally speaking, the fibres of the motor tract pass to the nuclei of the motor nerves on the opposite side of the brain or medulla spinalis, a fact which explains why a lesion involving the motor area of one side causes paralysis of the muscles of the opposite side of the body. As already stated (p. 755) there is experimental and clinical evidence to show that a few of the cerebrospinal fibres do not decussate (uncrossed fibres). There is a break in the continuity of the motor chain: in the case of the cerebral nerves this break occurs in the nuclei of these nerves; and in the case of the spinal nerves, in the anterior grey column of the medulla spinalis. For clinical purposes it is convenient to emphasise this break and divide the motor tract into two portions: (1) a series of *upper motor neurons* which comprises the motor cells in the cortex and their descending fibres down to the nuclei of the motor nerves; (2) a series of *lower motor neurons* which includes the cells of the nuclei of the motor cerebral nerves and the cells of the anterior columns of the medulla spinalis and their axis-cylinder processes to the periphery.*

SENSORY TRACT (fig. 798).

Sensory impulses are conveyed to the medulla spinalis through the posterior roots of the spinal nerves. On entering the medulla spinalis these root-fibres divide into descending and ascending branches; the descending branches soon enter and ramify in the grey substance: some of the ascending branches also enter and ramify in the grey substance, but others are continued directly into the posterior funiculi, where they form the fasciculus gracilis and fasciculus cuneatus. Fibres arise from the cells of the dorsal nucleus (Clarke's column), cross the middle line, and ascend in the superficial anterolateral fasciculus. The fibres of the fasciculus gracilis and fasciculus cuneatus end by arborising around the cells of the nucleus gracilis and nucleus cuneatus in the medulla oblongata, and from these cells the fibres of the medial lemniscus take origin and cross to the opposite side in the *sensory decussation*. The medial lemniscus is then joined by the superficial anterolateral fasciculus, the fibres of which have already crossed in the medulla spinalis, and in its further course, the medial lemniscus receives fibres from the terminal nuclei of the cerebral sensory nerves of the opposite side, with the exception of the terminal nuclei of the cochlear nerve. Ascending through the cerebral peduncle, the medial lemniscus gives off a few fibres to the lentiform nucleus and insula, but the greater part of it is carried into the thalamus, where its fibres end. From the cells of the thalamus the fibres of the third link in the chain arise and pass to the cerebral cortex. The fibres from the terminal nuclei of the cochlear nerve pass upwards

* As already mentioned (footnote, p. 755), a neuron in the posterior column of the medulla spinalis is probably interposed between each upper and lower motor neuron.

in the lateral lemniscus, and are carried through the occipital part of the internal capsule to the temporal lobe. Further, the superficial anterolateral fasciculus gives off fibres which reach the cerebellum through the brachium conjunctivum. It will be evident, therefore, that in most cases there are three cell-stations

FIG. 798.—The sensory tract. (Modified from Poirier.)

interposed in the course of the sensory impulses. For clinical purposes, therefore, three neurons are described: (1) the *lowest sensory neurons* which comprise the cells of the posterior root ganglia and their peripheral and central processes; (2) the *intermediate sensory neurons* which are the cells of the nucleus gracilis and nucleus cuneatus and their processes; (3) the *highest sensory neurons* which are the cells of the thalami and the fibres passing from these to the cerebral cortex.

Applied Anatomy.—The chief symptoms of diseases of the brain and medulla spinalis depend upon the particular systems of neurons picked out for attack, and some of them may be briefly summarised as follows. *Motor paralysis* of the *spastic* type, with rigidity of the muscles and increased reflexes, follows destruction of the upper motor neurons; *flaccid* paralysis, with loss of the reflexes and rapid muscular atrophy, follows destruction of the lower motor neurons. *Sensory paralysis* follows injury to any part of the sensory path; in tabes it is due to injury of the lowest sensory neurons, in hemiplegia to destruction of the highest sensory axon as it traverses the occipital part of the internal capsule. *Dissociation of sensations*, or the loss of some forms of sensation while others remain unimpaired, is seen in a number of conditions such as tabes or syringomyelia; it shows that the paths through which various forms of sensation travel to the brain are different. *Abnormalities of reflex actions* are of very great help in the diagnosis of nervous complaints. The numerous *superficial or skin reflexes* (e.g. the scapular, irritation of the skin over the scapula produces contraction of the scapular muscles; the abdominal, stroking the abdomen causes its retraction; the cremasteric, stroking the inner side of the thigh causes retraction of the testis on that side; the plantar, tickling the sole of the foot brings on plantar flexion of the toes), if present, show that the reflex arcs on whose integrity their existence depends are intact; but they often are absent in health and so cannot be trusted to indicate disease. The *deep reflexes* or *tendon reactions*, such as the knee-jerk, or the tendo calcaneus jerk, are increased in chronic degeneration of, or gradually increasing pressure on, the cerebrospinal fibres (upper motor neuron), in nervous or hysterical patients, and when the irritability of the cells of the anterior column (lower motor neuron) is increased, as happens in tetanus or in poisoning by strychnine. They are lost when the lower motor or lower sensory neurons are diseased, and in a few other conditions; absence of the knee-jerk is very rare in health, and suggests disease in some part of its reflex arc, in the third and fourth lumbar segments of the cord, or else, more rarely, grave intracranial or spinal disease cutting off the lower from the higher nervous centres. The *organic reflexes* of the pupil, bladder, and rectum are of the greatest practical importance. The commonest defect in the reflexes of the pupil is reflex iridoplegia, or failure to contract on exposure to light, without failure to contract on convergence or accommodation ('Argyll Robertson' pupil). The pupil is also contracted (miosis), and may or may not dilate when the skin of the neck is pinched (the ciliospinal reflex). Micturition is a spinal reflex much under the control of the brain; if the centre for micturition in the second sacral segment is destroyed the sphincter and the walls of the bladder are paralysed, the bladder becomes distended with urine, and incontinence from overflow results. If this centre escapes injury but is cut off more or less completely from impulses descending to it from above, there will be more or less interference with micturition. This varies in degree from the 'precipitate micturition' of tubercular patients, who must perforce hurry to pass water the moment the impulse seizes them, to the state of 'reflex incontinence,' when the bladder automatically empties itself from time to time, almost without the patient's knowledge. Defecation is a very similar spinal reflex, and is liable to very similar disorders of function.

The *upper motor neuron* (p. 836) is affected in hemiplegia, the *lower motor neuron* (p. 836) in infantile spinal paralysis; both these systems of neurons are diseased together in the somewhat rare disorders known as amyotrophic lateral sclerosis and progressive muscular atrophy. The chief symptom here is wasting and weakness in certain groups of muscles; the palsy will be flaccid, with loss of the reflexes, or spastic, with increased reflexes, according as the degeneration mainly involves the lower or the upper motor neuron. The sphincters are affected only in the later stages of these diseases.

Pathological changes in the *lowest sensory neuron* are the cause of tabes dorsalis or locomotor ataxy, which occurs almost entirely in adults who have had syphilis. In the early or pre-ataxic stage the patient may exhibit the Argyll Robertson pupil (see above), and loss of knee-jerks, and complain of sharp, stabbing pains ('lightning pains') in the limbs, difficult or precipitate micturition, and sometimes of severe and painful attacks of indigestion (gastric crises). In the second or ataxic stage, coming on perhaps years later, he will complain, in addition, of interference with his powers of getting about and turning, although his muscular strength is well preserved. He is unable to stand steady with his eyes shut or in the dark, his gait becomes exaggerated and stamping in character, he has to use a stout stick to walk with, and he may suffer from painful crises in various parts of the body. Control over the sphincters is further weakened, and on examination there will be found marked incoordination of the limbs, zones of anaesthesia about the trunk or down the limbs, and marked analgesia (or insensitiveness to pain) when pressure is applied to the bones, tendons, trachea, tongue, eyeballs, mammae, and testes. The ataxy progresses till the third or bedridden stage is reached; control over the sphincters is still further lost, and the patient is likely to die of intercurrent disease or of general paralysis of the insane.

No nervous disease is recognised as dependent upon degeneration of either the *intermediate* or *highest sensory neuron*.

MENINGES OF THE BRAIN AND MEDULLA SPINALIS

The brain and the medulla spinalis are enveloped by three membranes, named from without inwards: the dura mater, the arachnoid, and the pia mater.

R. THE DURA MATER

The dura mater is a thick and dense inelastic membrane. The portion of it which encloses the brain (cerebral dura mater) differs in several particulars from that which surrounds the medulla spinalis (spinal dura mater), and

FIG. 799.—The dura mater and its processes exposed by removing a part of the right half of the skull, and the brain.

therefore it is necessary to describe them separately; the two parts, however, form one complete membrane, and are continuous with one another at the foramen magnum.

The cerebral dura mater lines the interior of the skull, and serves the two-fold purpose of an internal periosteum to the bones, and a protective membrane for the brain. It is composed of two layers, an inner or meningeal and an outer or endosteal; these are closely united, except along certain lines where they are separated by the blood sinuses which drain the blood from the brain (p. 680). The dura mater adheres to the inner surfaces of the cranial

bones, and sends blood-vessels and fibrous processes into them. These blood-vessels and fibrous processes are torn across when the dura mater is detached, and the outer surface of the latter presents a rough and fibrillated appearance. The inner surface, on the other hand, is smooth and lined by a layer of endothelium. The adhesion of the dura mater is most marked at the sutures, at the base of the skull and around the foramen magnum. It is continuous through the sutures with the pericranium, and through the superior orbital fissure with the periosteal lining of the orbital cavity. It sends tubular sheaths on the cerebral nerves as the latter pass through the foramina at the base of the skull; outside the skull these sheaths fuse with the epineurium of the nerves; the sheath surrounding the optic nerve blends anteriorly with the sclera of the bulb of the eye.

FIG. 800.—The tentorium cerebelli. Seen from above.

The dura mater sends inwards four processes which divide the cavity of the skull into a series of freely communicating spaces for the lodgment and protection of the brain. These processes consist of reduplications of the inner or meningeal layer of the membrane and are named the *falx cerebri*, the *tentorium cerebelli*, the *falx cerebelli*, and the *diaphragma sellæ*.

The *falx cerebri* (fig. 799), so named from its sickle-like form, is a strong, arched process of dura mater which descends vertically in the longitudinal fissure between the cerebral hemispheres. It is narrow in front, where it is fixed to the crista galli of the ethmoidal bone; and broad behind, where it is attached to the middle line of the upper surface of the *tentorium cerebelli*; the narrow, anterior part is thin, and is frequently perforated by numerous apertures. Its upper margin is convex, and attached to the inner surface of the skull on either side of the middle line, as far back as the internal occipital protuberance; the superior sagittal sinus runs along this margin. Its lower

margin is free and concave, and contains the inferior sagittal sinus. The straight sinus runs along its attachment to the tentorium cerebelli.

The *tentorium cerebelli* (fig. 800) is an arched lamina of dura mater which covers the superior surface of the cerebellum, and supports the occipital lobes of the brain. Its concave, anterior border is free, and bounds a large oval opening, the *incisura tentorii*, which is occupied by the mesencephalon. Its convex, posterior border is attached behind to the lips of the transverse sulci on the inner surface of the occipital bone, and there encloses the transverse sinuses; in front, to the superior angle of the petrous part of the temporal bone on either side, enclosing the superior petrosal sinuses. At the apex of the petrous part of the temporal bone the free and attached borders cross one another, and are continued forwards to be fixed to the anterior and posterior clinoid processes respectively. As already stated, the posterior border of the falx cerebri is attached to the median line of the upper surface of the tentorium cerebelli, and the straight sinus lies in this line of attachment.

The *falx cerebelli* is a small, medially placed triangular process of dura mater which is situated below the tentorium cerebelli, and projects forwards into the posterior cerebellar notch. Its base, directed upwards, is attached to the posterior part of the tentorium; its posterior margin contains the occipital sinus, and is attached to the internal occipital crest; its apex frequently divides into two small folds, which are lost on the sides of the foramen magnum.

The *diaphragma sellæ* is a small circular horizontal fold of dura mater, which roofs the sella turcica and almost completely covers the hypophysis; a small opening in its centre transmits the infundibulum.

Structure.—The cranial dura mater consists of white fibrous tissue and elastic fibres arranged in flattened laminae which are imperfectly separated by lacunar spaces and blood-vessels into the endosteal and meningeal layers, already referred to. The endosteal layer is the internal periosteum for the cranial bones, and contains the blood-vessels for their supply. At the margin of the foramen magnum it is continuous with the periosteum lining the vertebral canal. The meningeal layer is lined on its inner surface by a layer of nucleated endothelium.

The arteries of the dura mater are very numerous. Those in the anterior fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid arteries; and a branch from the middle meningeal artery. Those in the middle fossa are the middle and accessory meningeal branches of the internal maxillary artery; a branch from the ascending pharyngeal artery, which enters the skull through the foramen lacerum; branches from the internal carotid artery, and a recurrent branch from the lacrimal artery. Those in the posterior fossa are meningeal branches from the occipital artery, one entering the skull through the jugular foramen, and another through the mastoid foramen; the posterior meningeal from the vertebral artery; occasional meningeal branches from the ascending pharyngeal artery, entering the skull through the jugular foramen and hypoglossal canal; and a branch from the middle meningeal artery.

The veins returning the blood from the cranial dura mater anastomose with the diploic veins and end in the cranial blood-sinuses. Many of the meningeal veins do not open directly into the sinuses, but indirectly through a series of ampullæ, termed *venous lacunæ*. These lacunæ are found on either side of the superior sagittal sinus, especially near its middle portion, and are often invaginated by arachnoidal granulations; they also exist near the transverse and straight sinuses. They communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The nerves of the cerebral dura mater are filaments from the semilunar ganglion of the trigeminal nerve, from the ophthalmic, maxillary, mandibular, vagus, and hypoglossal nerves, and from the sympathetic.

The spinal dura mater (figs. 801, 804) forms a loose sheath around the medulla spinalis, and represents only the inner or meningeal layer of the cerebral dura mater; the outer or endosteal layer ceases at the foramen magnum, its place being taken by the periosteum lining the vertebral canal. The spinal dura mater is separated from the wall of the vertebral canal by a space, the *epidural space*, which contains a quantity of loose areolar tissue and a plexus of veins; the situation of these veins between the dura mater and the periosteum of the vertebrae corresponds therefore to that of the cranial sinuses between the meningeal and endosteal layers of the cerebral dura mater. The spinal dura mater is attached to the circumference of the foramen magnum, and to the second and third cervical vertebrae; it is also connected by fibrous

slips to the posterior longitudinal ligament of the vertebræ, especially near the lower end of the vertebral canal. The subdural cavity ends at the lower

FIG. 801.—The medulla spinalis and its membranes.

border of the second sacral vertebra; below this level the dura mater closely invests the filum terminale and descends to the back of the coccyx, where it blends with the periosteum. The dura mater is continued in the form of tubular prolongations on the roots of the spinal nerves and on to the complete spinal nerves as they pass through the intervertebral foramina. These prolongations are short in the upper part of the vertebral column, but gradually become longer below.

Structure.—The spinal dura mater resembles in structure the meningeal layer of the cranial dura mater; it consists of white fibrous and elastic tissue arranged in bands or lamellæ which, for the most part, are parallel with one another and have a longitudinal arrangement. Its internal surface is smooth and covered by a layer of endothelium. It is sparingly supplied with blood-vessels and nerves.

THE ARACHNOID

The arachnoid is a delicate membrane enveloping the brain and medulla spinalis and lying between the pia mater internally and the dura mater externally. It is separated from the dura mater by the *subdural space*, but here and

there this space is traversed by isolated connective tissue trabeculæ, which are most numerous on the posterior surface of the medulla spinalis. It is separated from the pia mater by the *subarachnoid cavity* which is filled with cerebrospinal fluid.

The arachnoid surrounds the cerebral and spinal nerves, and encloses them in loose sheaths as far as their points of exit from the skull and vertebral canal.

The *cerebral part of the arachnoid* invests the brain loosely, and does not dip into the sulci between the gyri, nor into the fissures, with the exception of the longitudinal. On the upper surface of the brain it is thin and transparent; at the base it is thicker, and slightly opaque towards the central part, where it extends between the two temporal lobes in front of the pons, so as to leave a considerable interval between it and the pia mater.

The *spinal part of the arachnoid* (figs. 801, 804) is a thin, delicate, tubular membrane loosely investing the medulla spinalis. Above, it is continuous with the cerebral arachnoid; below, it widens out and invests the cauda equina and the nerves proceeding from it.

Structure.—The arachnoid consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. Vessels of considerable size, but few in number, and, according to Boeckdalek, a rich plexus of nerves derived from the motor root of the trigeminal, the facial, and the accessory nerves, are found in the cerebral part of the arachnoid.

The *subarachnoid cavity* is the interval between the arachnoid and pia mater. It contains the cerebrospinal fluid and the larger blood-vessels of the brain, and is traversed by a spongy tissue, consisting of delicate trabeculæ of connective tissue, which connect the arachnoid to the pia mater. This cavity is small on the surface of the hemispheres of the brain; on the summits of the gyri the pia mater and the arachnoid are in close contact; but where the arachnoid bridges the sulci triangular spaces are left, in which the subarachnoid trabecular tissue is found. At certain parts of the base of the brain, the arachnoid is separated from the pia mater by wide intervals, which communicate freely with each other and are named *subarachnoid cisternæ*; in these the subarachnoid tissue is less abundant.

Subarachnoid cisternæ (fig. 802).—The *cisterna cerebellomedullaris* (*cisterna magna*) is triangular on sagittal section, and is formed by the arachnoid bridging the wide interval between the medulla oblongata and the under surfaces of the hemispheres of the cerebellum; it is continuous with the subarachnoid cavity of the medulla spinalis at the level of the foramen magnum. The *cisterna pontis* is a considerable space on the ventral aspect of the pons. It contains the basilar artery, and is continuous behind with the subarachnoid cavity of the medulla spinalis, and with the *cisterna cerebellomedullaris*, and in front of the pons with the *cisterna interpeduncularis*. The *cisterna interpeduncularis* (*cisterna basalis*) is a wide cavity where the arachnoid extends across between the two temporal lobes. It encloses the cerebral peduncles and the structures in the interpeduncular fossa, and contains the arterial circle of Willis. Anteriorly, the *cisterna interpeduncularis* is continuous with the *cisterna chiasmatis* which lies in front of the optic chiasma and is prolonged on to

FIG. 802.—A diagram showing the positions of the three principal subarachnoid cisternæ.

the upper surface of the corpus callosum; here the arachnoid stretches from one cerebral hemisphere to the other immediately beneath the free border of the falx cerebri, and thus leaves a space in which the anterior cerebral arteries are contained. The *cisterna fossæ cerebri lateralis* contains the middle cerebral artery, and is formed in front of either temporal lobe by the arachnoid bridging the lateral cerebral fissure. The *cisterna venæ magnæ cerebri* occupies the interval between the splenium of the corpus callosum and the superior surface of the cerebellum; it extends between the layers of the tela chorioidea of the third ventricle and contains the great cerebral vein.

The subarachnoid cavity communicates with the general ventricular cavity of the brain by three openings: one, the *foramen of Majendie*, is in the middle line at the inferior part of the roof of the fourth ventricle; the other two are at the extremities of the lateral recesses of that ventricle, behind the upper roots of the glossopharyngeal nerves. It is stated by Meckel that the lateral ventricles also communicate with the subarachnoid cavity at the apices of their inferior cornua. There is no direct communication between the subdural and subarachnoid cavities.

The spinal part of the subarachnoid cavity is a wide interval, and is largest at the lower part of the vertebral canal, where the arachnoid encloses the nerves which form the cauda equina. Above, it is continuous with the cranial subarachnoid cavity; below, it ends at the level of the lower border of the second sacral vertebra. It is partially divided by a longitudinal septum,

the *subarachnoid septum*, which connects the arachnoid with the pia mater opposite the posterior median sulcus of the medulla spinalis, and forms a partition, incomplete and cribriform above, but more complete in the thoracic region. The spinal subarachnoid cavity is further subdivided by the *ligamentum denticulatum*, which will be described with the pia mater.

The cerebrospinal fluid is a clear, slightly alkaline fluid, with a specific gravity of about 1007. It contains in solution inorganic salts similar to those in the blood-plasma, and also traces of protein and glucose. It supports and protects the delicate structures of the brain and medulla spinalis, maintains a uniform pressure on them, and probably acts as their nutritive fluid.

It is produced by the action of the secreting cells which cover the chorioid plexuses of the brain, and is normally present at a certain pressure which is not dependent on the arterial or venous blood-pressure. Its secretion may be increased (a) by an excess of carbonic acid, (b) by volatile anæsthetics, or (c) by an extract of the chorioid plexuses or of the brain. Dyes added to the fluid travel along the courses of certain cerebral nerves (especially the olfactory nerves) but not along the spinal nerves.

When readily diffusible substances are introduced into the subcerebellar part of the subarachnoid cavity they produce typical physiological actions almost as rapidly as when injected into the venous circulation. The diffusion of such substances is, on the contrary, extremely slow in the lower spinal region.*

Applied Anatomy.—In various diseases, such as syphilis, meningitis, and infantile paralysis, changes take place in the chemical nature of the substances dissolved in the cerebrospinal fluid, or in the various cells found suspended in it; and these alterations are often of service in diagnosis.

Evidence of great value in the diagnosis of meningitis may sometimes be obtained by puncturing the spinal membranes and withdrawing some of the cerebrospinal fluid; moreover, the operation of lumbar puncture is in many cases curative, under the supposition that the draining of some of the cerebrospinal fluid relieves the patient by diminishing the intracranial pressure. The operation is performed by inserting a trocar, of the smallest size, between the laminae of the third and fourth, or of the fourth and fifth lumbar vertebrae, through the ligamentum flavum. The medulla spinalis, even of a child at birth, does not reach below the third lumbar vertebra, and therefore the canal may be punctured between the third and fourth lumbar vertebrae without any risk of injuring this structure. The point of puncture is indicated by laying the patient on the side and dropping a perpendicular line from the highest point of the iliac crest; this will cross the upper border of the spinous process of the fourth lumbar vertebra, and will indicate the level at which the trocar should be inserted a little to one side of the middle line. The puncture may require to be repeated more than once, and the greatest precaution must be taken not to allow septic infection of the meninges. If there be any appreciable increase of pressure, the fluid will flow through the trocar with the greatest freedom.

In addition to the constitutional signs and symptoms of fever, *acute spinal meningitis* exhibits certain characteristic features. Pain and tenderness to pressure along the vertebral column are common, and so are pains in the limbs or round the trunk from irritation of the posterior nerve-roots by the inflammatory products. Irritation of the anterior nerve-roots is shown by the increased tone of the muscles, which may go on to the point where they pass into a state of spasm with much-increased reflexes; this is often seen in the retraction of the head and neck. Later in the disease the reflexes are often lost, when, also, the urine and feces may be passed involuntarily.

Spinal anæsthesia can be induced by injecting certain substances, especially stovaine, into the cerebrospinal fluid. It is done by means of a syringe attached to a lumbar puncture needle, and is especially valuable, when from any cause the administration of a general anæsthetic is inadvisable; but any operation below the level of the umbilicus (10th thoracic nerve) can be performed painlessly by this method.

The arachnoideal granulations (*glandulae Pacchionii*) (fig. 803) are small fleshy-looking elevations, usually collected into clusters of variable size, which are present upon the outer surface of the dura mater, in the vicinity of the superior sagittal sinus, and in some other situations. Upon laying open the sagittal sinus and the venous lacunae on either side of it, granulations will be found protruding into their interior. They are very rarely developed until the third year; they are usually found after the seventh year; and from this period they increase in number and size as age advances. They are enlarged normal villi of the arachnoid, which as they grow push the thinned dura mater before them, and cause absorption of the bone from pressure, and so produce the pits or depressions on the inner wall of the calvarium.

*Consult articles by Dixon and Halliburton, *Journal of Physiology*, vol. x., and Halliburton, *British Medical Journal*, Nov. 4, 1918.

Structure.—An arachnoideal granulation consists of the following parts : 1. In the interior is a core of subarachnoid tissue, continuous with the meshwork of the general subarachnoid tissue through a narrow pedicle, by which the granulation is attached to the arachnoid. 2. Around this tissue is the arachnoid membrane. 3. Outside this is the thinned wall of the lacuna, which is separated from the arachnoid by the subdural cavity. 4. If the granulation projects into the sagittal sinus, it

Fig. 803.—A diagrammatic representation of a section across the top of the skull, showing the membranes of the brain, &c. (Modified from Testut.)

is covered by the greatly thinned wall of the sinus. Fluid injected into the sub-arachnoid cavity will find its way into these granulations, and it has been found experimentally that fluid passes by osmosis from the granulations into the venous sinuses into which they project.

THE PLA MATER

The **pia mater** closely invests the brain and medulla spinalis; it is a vascular membrane, consisting of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. The *cerebral pia mater* invests the entire surface of the brain, dips between the cerebral gyri and cerebellar laminæ, and is invaginated to form the tela chorioidea of the third ventricle, and the chorioid plexuses of the lateral and third ventricles (pp. 826, 827); as it passes over the roof of the fourth ventricle, it forms the tela chorioidea and the chorioid plexuses of this ventricle (p. 785). Upon the surfaces of the hemispheres, where it covers the grey substance, it gives off from its deep surface a multitude of sheaths around the minute vessels that extend perpendicularly for some distance into the cerebral substance. On the cerebellum the membrane is more delicate; the vessels from its deep surface are shorter, and its relations to the cortex are not so intimate.

The *spinal pia mater* (figs. 801, 804) is thicker, firmer, and less vascular than the cerebral pia mater; this is due to the fact that it consists of two layers, the outer or additional one being composed of bundles of connective tissue fibres, arranged for the most part longitudinally. Between the layers are cleft-like spaces which communicate with the subarachnoid cavity, and a number of blood-vessels which are enclosed in perivascular lymphatic sheaths.

The spinal pia mater covers the entire surface of the medulla spinalis, and is intimately adherent to it; in front it sends a process backwards into the anterior fissure. A longitudinal fibrous band, called the *linea splendens*, extends along the middle line of the anterior surface, and a somewhat similar band, the *ligamentum denticulatum*, is situated on either side. Below the conus medullaris the pia mater is continued as a long slender filament (*filum terminale*), which descends through the centre of the mass of nerves forming the cauda equina. The *filum terminale* blends with the dura mater at the level of the lower border of the second sacral vertebra, and extends downwards as far as the base of the coccyx, where it fuses with the periosteum; it assists in maintaining the medulla spinalis in position during the movements of the trunk, and is, from this circumstance, called the *central ligament* of the medulla spinalis.

FIG. 804.—A diagrammatic transverse section of the medulla spinalis and its membranes.

The pia mater forms sheaths for the cerebral and spinal nerves; these sheaths are closely connected with the nerves, and blend with their common membranous investments.

The *ligamentum denticulatum* (fig. 801) is a narrow fibrous band situated on either side of the medulla spinalis throughout its entire length, and separating the anterior from the posterior nerve-roots. Its medial border is continuous with the pia mater at the side of the medulla spinalis. Its lateral border presents a series of triangular tooth-like processes, the points of which are fixed at intervals to the dura mater. These processes are twenty-one in number, on either side. The first process crosses behind the vertebral artery at the point where that vessel pierces the dura mater, and is separated by the artery from the first cervical nerve; it is attached to the dura mater immediately above the margin of the foramen magnum, 1.25 cm. behind the hypoglossal nerve. The last process is between the exits of the twelfth thoracic and first lumbar nerves, and consists of a narrow oblique band running downwards and lateralwards from the conus medullaris (Parsons *).

CEREBRAL NERVES

There are twelve pairs of cerebral nerves, which are named from before backwards as follows:

- | | | |
|----------------------------|------------------|------------------------|
| 1st. Olfactory. | 5th. Trigeminal. | 9th. Glossopharyngeal. |
| 2nd. Optic. | 6th. Abducent. | 10th. Vagus. |
| 3rd. Oculomotor. | 7th. Facial. | 11th. Accessory. |
| 4th. Trochlear (Pathetic). | 8th. Acoustic. | 12th. Hypoglossal. |

These nerves are attached to the brain, and are transmitted through openings in the base of the cranium. The fibres of the nerves can be traced into the

* *Proceedings of the Anatomical Society of Great Britain and Ireland, 1915.*

substance of the brain to special nuclei of grey substance. The motor or efferent cerebral nerves arise within the brain from groups of nerve-cells which constitute their *nuclei of origin*. The sensory or afferent cerebral nerves arise from nerve-cells outside the brain; these nerve-cells may be grouped to form ganglia on the trunks of the nerves, or may be situated in peripheral sensory organs such as the nose and eye. The centrally directed processes of the cells run into the brain, and there end by arborising around nerve-cells, which are grouped to form *nuclei of termination*. The nuclei of origin of the motor nerves and the nuclei of termination of the sensory nerves are brought into relationship with the cerebral cortex, the former through the geniculate fibres of the internal capsule, the latter through the lemniscus. The geniculate fibres of the internal capsule arise from the cells of the motor area of the cortex; they cross the middle line, and end by arborising around the cells of the nuclei of origin of the motor cerebral nerves. On the other hand, fibres arise from the cells of the nuclei of termination of the sensory nerves, and, after crossing to the opposite side, join the lemniscus, and thus connect the nuclei of termination, directly or indirectly, with the cerebral cortex.

FIG. 805.—The nerves of the septum of the nose. Right side.

OLFACTORY NERVES (fig. 805)

The olfactory nerves, or nerves of smell, are distributed to the mucous membrane of the olfactory region of the nasal cavity; this region comprises

FIG. 806.—A plan of the olfactory neurons.

the superior nasal concha, and the opposed part of the nasal septum. The nerve-fibres originate from the central or deep processes of the olfactory cells

of the nasal mucous membrane, and are collected into bundles which cross one another in various directions, and thus give rise to the appearance of a plexiform network in the mucous membrane. They are then collected into about twenty branches, which pierce the lamina cribrosa of the ethmoidal bone in a lateral and a medial group, and end in the glomeruli of the olfactory bulb (fig. 806). Each branch receives tubular sheaths from the dura mater and pia mater, the former being continued into the periosteum of the nose, the latter into the neurolemma of the nerve.

The olfactory nerves are non-medullated, and consist of axis-cylinders surrounded by nucleated sheaths, in which, however, there are fewer nuclei than in the sheaths of ordinary non-medullated nerve-fibres.

The olfactory centre in the cortex is generally associated with the rhinencephalon (p. 812).

Applied Anatomy.—In severe injuries to the head involving the anterior fossa of the base of the skull, the olfactory bulb may become separated from the olfactory nerves or the nerves may be torn, thus producing loss of smell (*anosmia*), and with this there is a considerable loss in the sense of taste, since much of the perfection of the sense of taste is due to the substances being also odorous, and simultaneously exciting the sense of smell.

Anosmia often occurs after influenza or other acute infection of the nose. Parosmia, or a perversion of the sense of smell, may occur in lesions of the cortical olfactory centres, or in insanity.

OPTIC NERVE (fig. 807)

The optic nerve or nerve of sight is distributed exclusively to the bulb of the eye. Most of its fibres are afferent and originate in the nerve-cells of the ganglionic layer of the retina (p. 962), but a few are efferent and spring from nerve-cells in the lower visual centres of the brain (p. 797).

The fibres of the optic nerve form the innermost layer (stratum opticum) of the retina; they converge to the optic disc, and then pierce the chorioid

FIG. 807.—The left optic nerve, the optic chiasma, and the optic tracts.

coat and the lamina cribrosa at the posterior part of the bulb of the eye, about 3 or 4 mm. to the nasal side of its centre. As the nerve-fibres traverse the lamina cribrosa they receive their medullary sheaths and run in bundles which are collected to form the optic nerve.

The optic nerve is directed backwards and medialwards through the posterior part of the orbital cavity. It then runs through the optic foramen into the cranial cavity and joins the optic chiasma.

The part of the nerve contained in the orbital cavity is about 25 mm. long. It is surrounded by the rectus muscles, but is separated from them by a quantity of fat in which the ciliary vessels and nerves are lodged. The ciliary ganglion lies between the nerve and the Rectus lateralis muscle. The nerve is pierced below, at a distance of about 12 mm. behind the bulb of the eye, by the central artery and

vein of the retina, which are then directed forwards in the centre of the nerve to the optic disc. Near the optic foramen the ophthalmic artery runs forwards and medialwards across the nerve. In the optic foramen this artery lies beneath and laterally to the nerve, which is here separated medially from the sphenoidal and posterior ethmoidal air-sinuses by a thin lamina of bone.

The intracranial part of the optic nerve, about 10 mm. long, runs backwards and medialwards from the optic foramen to the optic chiasma. Above it are the posterior parts of the olfactory tract and gyrus rectus, and, near the chiasma, the anterior cerebral artery. On its lateral side is the internal carotid artery.

The optic nerve consists mainly of fine medullated fibres, and is enclosed in three sheaths which are continuous with the membranes of the brain. It is in fact an outlying part of the white substance of the brain.

The *outer sheath*, derived from the dura mater, is thick and fibrous, and blends anteriorly with the sclera of the bulb of the eye. The *intermediate sheath*, derived from the arachnoid membrane, is thin and delicate. It is separated from the outer sheath by a narrow lymph-space which is continuous posteriorly with the subdural space, and from the inner sheath by a wider space which is continuous posteriorly with the subarachnoid cavity. The *inner sheath*, derived from the pia mater, is vascular and closely invests the nerve. From its deep surface septa pass into the nerve and subdivide and

FIG. 808.—A scheme showing the central connexions of the optic nerves and optic tracts.

reunite to enclose what appear, in transverse sections of the nerve, as polygonal areas which are occupied by the bundles of nerve-fibres. From the inner sheath also, an investment is carried on the central vessels of the retina as far as the optic disc.

The **optic chiasma** or **commissure**, somewhat quadrilateral in shape, lies above the tuberculum sellæ and the anterior part of the diaphragma sellæ, some distance behind the so-called sulcus chiasmatis of the sphenoidal bone. It forms the anterior part of the floor of the third ventricle and is in relation above with the lamina terminalis, behind with the tuber cinereum, and laterally with the anterior perforated substance and the internal carotid artery.

The fibres of the optic nerve undergo a partial decussation in the optic chiasma (fig. 808). The fibres from the medial (nasal) half of the retina cross

the middle line in the central part of the chiasma and enter the optic tract of the opposite side. The fibres from the lateral (temporal) half of the retina do not cross, but are continued backwards, through the lateral part of the chiasma, into the optic tract of the same side. The posterior part of the chiasma consists of fibres which cross the middle line, but do not form parts of the optic nerves; these fibres connect the medial geniculate bodies of opposite sides and constitute what is known as the *Commissure of Gudden*.

The optic tract is a cylindrical bundle of nerve-fibres which runs backwards and lateralwards from the optic chiasma. It passes between the anterior perforated substance and the tuber cinereum, and reaches the under surface of the cerebral peduncle, where it becomes flat, and is attached to the peduncle by its anterior margin. It then winds round the peduncle and divides into a medial and a lateral root. The fibres of the medial root form the commissure of Gudden, already referred to, and pass to the medial geniculate body. The lateral and larger root ends in the lateral geniculate body, the pulvinar of the thalamus and the superior colliculus, which together constitute the *lower visual centres*. From the cells of these centres fibres, termed the *optic radiations*, are prolonged through the occipital part of the internal capsule to the *higher or cortical visual centre*, which is situated in the cuneus and in the neighbourhood of the calcarine fissure.

Some fibres are detached from the optic tract, and pass through the cerebral peduncle to the nucleus of the oculomotor nerve. These fibres are small, and may be regarded as afferent branches for the Sphincter pupillæ and Ciliaris muscles. Other fibres pass to the cerebellum through the brachia conjunctiva, while others end in the nuclei of the pons.

Applied Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and as a rule the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connexion with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease. (1) From its mode of development, and from its structure, the optic nerve must be regarded as a prolongation of the brain substance, rather than as an ordinary cerebral nerve. (2) It receives sheaths from the three cerebral membranes, and these sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid cavities respectively. The innermost sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters intimately into its structure. Thus inflammatory affections of the meninges or of the brain may readily extend along these spaces, or along the interstitial connective tissue in the nerve.

The optic neuritis or papillitis ("choked disc") that is often seen in cases of intracranial new growth with increased intracranial tension is probably caused by increased pressure in the vaginal sheath of the optic nerve, due to excess of fluid in the general subarachnoid space with which this sheath is in direct communication. If, as is the case, for example in the internal hydrocephalus seen as a complication of cerebro-spinal fever, there is no increase in the amount of fluid in the subarachnoid space, then there will be no optic neuritis although the intracranial tension may rise until it brings about the patient's death.

The course of the fibres in the optic chiasma has an important pathological bearing and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each optic tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time Charcot believes, and his view has met with general acceptance, that the fibres which do not decussate at the optic chiasma undergo decussation in the corpora quadrigemina, so that the lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed; whereas if one tract, say the right, be destroyed by disease, there will be blindness of the right half of both retinae.

An anteroposterior section through the chiasma would divide the decussating fibres, and would therefore produce blindness of the medial half of each eye; while a section at the margin of the side of the optic chiasma would produce blindness of the lateral half of the retina of the same side. An early symptom of tumour-growth in the hypophysis is pressure on the chiasma.

The optic nerve may also be affected in injuries or diseases involving the orbit; in fractures of the anterior fossa of the base of the skull; in tumours of the orbit itself, or those invading this cavity from neighbouring parts.

OCULOMOTOR NERVE (figs. 810, 811, 812)

The oculomotor nerve supplies all the ocular muscles, except the Obliquus superior and Rectus lateralis; it also supplies, through its connexion with the ciliary ganglion, the Sphincter pupillæ and the Ciliaris muscles.

The fibres of the oculomotor nerve arise from a nucleus which lies in the grey substance of the upper part of the floor of the cerebral aqueduct and extends in front of the aqueduct for a short distance into the floor of the third ventricle. From this nucleus the fibres pass forwards through the tegmentum, the red nucleus and the medial part of the substantia nigra, forming a series of curves with a lateral convexity, and emerge from the oculomotor sulcus on the medial side of the cerebral peduncle.

The nucleus of the oculomotor nerve does not consist of a continuous column of cells, but is broken up into a number of smaller nuclei, which are arranged in two groups, anterior and posterior. Those of the posterior group are six in number, five of which are symmetrical on the two sides of the middle line, while the sixth is centrally placed and is common to the nerves of both sides. The anterior group consists of two nuclei, an anteromedial and an anterolateral (fig. 809).

The nucleus of the nerve is said to send fibres through the medial longitudinal fasciculus to the facial nerve, for the supply of the Orbicularis oculi, Corrugator, and Frontalis muscles.* It is also connected with the nuclei of the trochlear and abducent nerves, with the cerebellum, the superior colliculus, and the cortex of the occipital lobe of the cerebrum.

The nucleus of the oculomotor nerve, considered from a physiological standpoint, can be subdivided into several smaller groups of cells, each group controlling a particular muscle. The nerves to the different muscles appear to take their origin from behind forwards as follows: Obliquus inferior, Rectus inferior, Rectus superior, Levator palpebræ superioris, and Rectus medialis; while from the anterior end of the nucleus the fibres for the Ciliaris and the Sphincter pupillæ take their origin.

On emerging from the brain, the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It passes between the superior cerebellar and posterior cerebral arteries, runs forward in the triangular interval between the free and attached borders of the tentorium cerebelli, and then pierces the dura mater in front of and lateral to the posterior clinoid process. It traverses the lateral wall of the cavernous sinus, above the trochlear nerve, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the ophthalmic division of the trigeminal. It then divides into two rami, which enter the orbit through the superior orbital fissure, between the two heads of the Rectus lateralis. Here the nerve is placed below the trochlear nerve and the frontal and lacrimal branches of the ophthalmic nerve, while the nasociliary nerve is placed between its two rami.

FIG. 809.—The different groups of cells which constitute, according to Perlia, the nucleus of origin of the oculomotor and trochlear nerves. (Testut.)

1. Posterior dorsal nucleus. 1'. Posterior ventral nucleus. 2. Anterior dorsal nucleus. 2'. Anterior ventral nucleus. 3. Central nucleus. 4. Nucleus of Edinger and Westphal. 5. Anteromedial nucleus. 6. Anterolateral nucleus. 8. Crossed fibres. 9. Trochlear nerve, with 9'. Its nucleus of origin, and 9''. Its decussation. 10. Third ventricle. M, M. Median line.

* See footnote, p. 790.

The *superior ramus*, the smaller, passes medialwards over the optic nerve, and supplies the Rectus superior and Levator palpebræ superioris. The *inferior ramus*, the larger, divides into three branches. One passes beneath the optic nerve to the Rectus medialis; another, to the Rectus inferior; the third and longest runs forwards between the Rectus inferior and Rectus lateralis to the Obliquus inferior. From the nerve to the Obliquus inferior a short thick branch is given off to the lower part of the ciliary ganglion, and forms its *short root*. All these branches enter the muscles on their ocular surfaces, with the exception of that to the Obliquus inferior, which enters the posterior border of the muscle.

FIG. 810.—A plan of the oculomotor nerve.

Applied Anatomy.—Paralysis of the oculomotor nerve may be the result of many causes, such as cerebral disease; or conditions causing pressure on the cavernous sinus; or periostitis of the bones entering into the formation of the superior orbital fissure. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebræ superioris being paralysed; (2) external strabismus, on account of the unopposed action of the Rectus lateralis and Obliquus superior, which are not supplied by the oculomotor nerve and are therefore not paralysed; (3) dilatation of the pupil, because the Sphincter pupillæ is paralysed; (4) loss of power of accommodation and of contraction on exposure to light, as the Sphincter pupillæ and the Ciliaris are paralysed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed; and (6) the patient will complain of the resulting diplopia, or double vision, the false image being higher than the true, and the separation of the two images increasing with medial movements. Occasionally paralysis may affect only a part of the nerve—that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Rectus medialis: accommodation for near objects only, from spasm of the Ciliaris; or miosis (contraction of the pupil) from irritation of the Sphincter pupillæ.

The oculomotor nerve is particularly liable to become involved in a syphilitic periarthritis, as it leaves the base of the brain, when passing between the posterior cerebral and superior cerebellar arteries; associated with locomotor ataxia various partial or complete paralyzes of the nerve are often seen.

TROCHLEAR NERVE (fig. 811)

The trochlear nerve, the smallest of the cerebral nerves, supplies the Obliquus superior oculi.

It arises from a nucleus situated in the floor of the cerebral aqueduct, opposite the upper part of the inferior colliculus. From its origin it runs downwards through the tegmentum, and then turns backwards into the upper part of the anterior medullary velum. Here it decussates with its fellow of the opposite side and emerges from the surface of the velum at the side of the frenulum veli, immediately behind the inferior colliculus.

The nerve is directed across the brachium conjunctivum cerebelli, and then winds forwards round the cerebral peduncle immediately above the pons, pierces the dura mater in the free border of the tentorium cerebelli, just behind, and lateral to, the posterior clinoid process, and passes forwards in the lateral wall of the cavernous sinus, between the oculomotor nerve and the ophthalmic division of the trigeminal. It crosses the oculomotor nerve, and enters the

orbit through the superior orbital fissure. It now becomes the highest of all the nerves, and lies medial to the frontal nerve. In the orbit it passes medialwards, above the origin of the Levator palpebræ superioris, and finally enters the orbital surface of the Obliquus superior.

In the lateral wall of the cavernous sinus the trochlear nerve forms communications with the ophthalmic division of the trigeminal and with the cavernous plexus of the sympathetic. In the superior orbital fissure it occasionally gives off a branch to the lacrimal nerve. It gives off a recurrent branch which passes backwards between the layers of the tentorium cerebelli and divides into two or three filaments which may be traced as far as the wall of the transverse sinus.

FIG. 811.—The nerves of the orbit, from above.

Applied Anatomy.—When the trochlear nerve is paralysed there is loss of function in the Obliquus superior, so that the patient is unable to turn his eye downwards and outwards. Should the patient attempt to do this, the eye of the affected side is rotated inwards, producing diplopia or double vision. Single vision exists in the whole of the field so long as the eyes look above the horizontal plane, but diplopia occurs on looking downwards. To counteract this the patient holds his head forwards, and also inclines it to the sound side.

TRIGEMINAL NERVE

The trigeminal nerve is the largest cerebral nerve. It is the sensory nerve of the face and of the greater part of the scalp, and the motor nerve of the muscles of mastication.

It is attached to the anterior or ventral surface of the pons, near its upper border, by a large *sensory*, and a small *motor*, root—the latter being placed medially and anteriorly to the former.

The fibres of the sensory root arise from the cells of the *semilunar ganglion* (Gasserian ganglion). This ganglion (figs. 811, 812) occupies a cavity (cavum Meckelii) in the dura mater covering the trigeminal impression near the apex of the petrous part of the temporal bone. The ganglion is somewhat crescentic in shape, with its convexity directed forwards and lateralwards. Medially, it is in relation with the internal carotid artery and the posterior part of the cavernous sinus. Beneath it are the motor root of the nerve and the greater superficial petrosal nerve. It receives filaments from the cavernous plexus of the sympathetic, and gives off twigs to the tentorium cerebelli.

The axis-cylinders of the cells of the semilunar ganglion divide into *peripheral* and *central* branches. The former are grouped to form the *ophthalmic* and *maxillary* nerves, and the sensory part of the *mandibular* nerve (the last is joined outside the cranium by the motor root of the nerve). The central branches constitute the fibres of the sensory root of the nerve, which leaves the concave margin of the ganglion, runs backwards and medialwards below the superior petrosal sinus and the tentorium cerebelli, and enters the pons. In the pons these fibres divide, like the fibres of the posterior roots of the spinal nerves, into ascending and descending branches. The ascending branches end

in the upper sensory nucleus of the trigeminal nerve, which is situated in the pons, on the lateral side of, and somewhat deeper than, the motor nucleus. The descending fibres form what is termed the *spinal tract* of the trigeminal nerve. This tract runs downwards through the pons into the medulla oblongata on the lateral side of a column of grey substance named the gelatinous substance of Rolando. As the tract descends, a succession of fibres leaves it and enters the gelatinous substance; the tract thus diminishes as it passes downwards, and finally ends in the upper part of the cervical portion of the medulla spinalis.

Medullation of the fibres of the sensory root begins about the fifth month of foetal life, but the whole of the fibres of the root are not medullated until the third month after birth.

The fibres of the *motor root* arise from two nuclei, an inferior and a superior. The *inferior* or *chief nucleus* is situated in the upper part of the pons, close to its dorsal surface, and along the line of the lateral margin of the rhomboid fossa. The *superior nucleus* consists of a strand of cells occupying the whole length of the lateral portion of the grey substance of the cerebral aqueduct. The fibres from this nucleus constitute the *mesencephalic root**; they descend through the mesencephalon, and, entering the pons, join with the fibres from the lower nucleus, and the motor root, thus formed, passes forwards through the pons to its point of emergence.

Four small ganglia are associated with the three divisions of the trigeminal nerve, viz.—the *ciliary ganglion* with the ophthalmic nerve; the *sphenopalatine ganglion* with the maxillary nerve; and the *otic* and *submaxillary ganglia* with the mandibular nerve.

OPHTHALMIC NERVE (figs. 811, 812)

The **ophthalmic nerve**, or first division of the trigeminal nerve, is a sensory nerve. It supplies branches to the bulb of the eye, the lacrimal gland and

FIG. 812.—The nerves of the orbit, and the ciliary ganglion, from the side.

the conjunctiva, to a part of the mucous membrane of the nasal cavity, and to the skin of the nose, eyelids, forehead, and scalp. It is the smallest division of the trigeminal nerve, and arises from the anteromedial part of the semilunar ganglion as a flattened band, about 2.5 cm. long, which passes forwards along the lateral wall of the cavernous sinus below the oculomotor and trochlear nerves; just before entering the orbit through the superior orbital fissure, it divides into three branches, *lacrimal*, *frontal*, and *nasociliary*.

The ophthalmic nerve is joined by filaments from the cavernous plexus of

* Recent observations indicate that the mesencephalic root of the trigeminal nerve contains some sensory fibres.

OPHTHALMIC NERVE

the sympathetic, and communicates with the oculomotor, trochlear, and abducent nerves; it gives off a recurrent branch (n. tentorii), which crosses the trochlear nerve, and passes between the layers of the tentorium.

The **lacrimal nerve** is the smallest branch of the ophthalmic nerve. It sometimes receives a filament from the trochlear nerve, but possibly this consists of fibres which have previously passed from the ophthalmic to the trochlear nerve. It enters the orbit through the narrowest part of the superior orbital fissure, runs along the upper border of the Rectus lateralis, with the lacrimal artery, and communicates with the zygomatic branch of the maxillary nerve. It enters the lacrimal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally it pierces the orbital septum, and ends in the skin of the upper eyelid, joining with filaments of the facial nerve.

The lacrimal nerve is occasionally absent, and its place is then taken by the zygomaticotemporal branch of the maxillary nerve. Sometimes the latter branch is absent, and a continuation of the lacrimal is substituted for it.

The **frontal nerve** is the largest branch of the ophthalmic nerve. It enters the orbit through the superior orbital fissure, and runs forwards between the Levator palpebrae superioris and the periosteum. Midway between the apex and base of the orbit it divides into two branches, a small supratrochlear and a larger supraorbital.

The **supratrochlear nerve** passes above the pulley of the Obliquus superior, and gives off a descending filament, to join the infratrochlear branch of the nasociliary nerve. It then escapes from the orbit between the pulley of the Obliquus superior and the supraorbital foramen, curves upwards on the forehead close to the bone, and sends filaments to the conjunctiva and skin of the upper eyelid; it then ascends under cover of the Corrugator and Frontalis, and divides into branches which pierce these muscles and supply the skin of the lower part of the forehead close to the middle line.

The **supraorbital nerve** passes through the supraorbital foramen, and gives off palpebral filaments to the upper eyelid. It then ascends upon the forehead, and ends in two branches, a medial and a lateral, which supply the skin of the scalp, reaching nearly as far back as the lambdoidal suture. These two branches are at first situated beneath the Frontalis; the medial branch perforates this muscle, the lateral branch pierces the galea aponeurotica. Both branches supply small twigs to the pericranium and to the mucous membrane of the frontal air-sinus.

The **nasociliary nerve** is intermediate in size between the frontal and lacrimal nerves, and is more deeply placed. It enters the orbit between the two heads of the Rectus lateralis, and between the superior and inferior rami of the oculomotor nerve. It passes across the optic nerve and runs obliquely beneath the Rectus superior and Obliquus superior, to the medial wall of the orbital cavity. Here, under the name of the *anterior ethmoidal nerve*, it passes through the anterior ethmoidal foramen and, entering the cavity of the cranium, traverses a shallow groove on the lateral margin of the front part of the lamina cribrosa of the ethmoidal bone, and runs down, through a slit at the side of the crista galli, into the nasal cavity where it lies in a groove on the inner surface of the nasal bone. It supplies *internal nasal branches* to the mucous membrane of the front part of the septum and lateral wall of the nasal cavity. Finally, it emerges, as the *external nasal branch*, between the lower border of the nasal bone and the lateral nasal cartilage, and, passing down beneath the Nasalis muscle, supplies the skin of the ala and apex of the nose.

The nasociliary nerve gives off the long root of the ciliary ganglion, the long ciliary, the infratrochlear, and the posterior ethmoidal nerves.

The *long root of the ciliary ganglion* usually arises from the nasociliary nerve between the two heads of the Rectus lateralis. It passes forwards on the lateral side of the optic nerve, and enters the posterosuperior angle of the ciliary ganglion; it is sometimes joined by a filament from the cavernous plexus of the sympathetic, or from the superior ramus of the trochlear nerve.

The *long ciliary nerves*, two or three in number, are given off from the nasociliary nerve, as it crosses the optic nerve. They accompany the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclera, and, running forwards between it and the chorioid, are distributed to the ciliary body, iris, and cornea.

The *infratrochlear nerve* is given off from the nasociliary nerve near the anterior ethmoidal foramen. It runs forwards along the medial wall of the orbit above the upper border of the Rectus medialis, and is joined, near the pulley of the Obliquus superior, by a filament from the supratrochlear nerve. It then escapes from the orbit beneath the pulley of the Obliquus superior; it supplies the skin of the eyelids and side of the nose, the conjunctiva, lacrimal sac, and caruncula lacrimalis.

The *posterior ethmoidal nerve* leaves the orbital cavity through the posterior ethmoidal foramen and gives twigs to the ethmoidal cells and sphenoidal sinus.

Ciliary ganglion.—The ciliary ganglion (figs. 810, 812) is a small, quadrangular, flattened ganglion, of a reddish-grey colour, and about the size of a pin's head; it is situated at the back part of the orbit, in some loose fat between the optic nerve and the Rectus lateralis muscle, lying generally on the lateral side of the ophthalmic artery.

Its *roots* are three in number, and enter its posterior border. One, the long or sensory root, is derived from the nasociliary nerve, and joins its postero-superior angle. The second, the short or motor root, is a thick nerve (occasionally divided into two parts) derived from the branch of the oculomotor nerve to the Obliquus inferior, and connected with the postero-inferior angle of the ganglion. The third, the sympathetic root, is a slender filament from the cavernous plexus of the sympathetic; it is frequently blended with the long root. According to Tiedemann, the ciliary ganglion receives a twig of communication from the sphenopalatine ganglion.

Its *branches* are the short ciliary nerves. There are delicate filaments, from six to ten in number, which arise from the forepart of the ganglion in two bundles connected with its superior and inferior angles; the lower bundle is the larger. They run forwards with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary nerves. They pierce the sclera around the entrance of the optic nerve, pass forwards in delicate grooves on the inner surface of the sclera, and are distributed to the Ciliaris muscle, iris, and cornea. Tiedemann described a small branch which penetrated the optic nerve with the arteria centralis retinae.

MAXILLARY NERVE (fig. 813)

The **maxillary nerve**, or second division of the trigeminal nerve, is a sensory nerve, and is intermediate in position and size between the ophthalmic and mandibular nerves. It begins at the middle of the semilunar ganglion as a flattened plexiform band, and, passing horizontally forwards in the lower part of the lateral wall of the cavernous sinus, leaves the skull through the foramen rotundum, where it becomes more cylindrical in form and firmer in texture. It then crosses the pterygopalatine fossa, inclines lateralwards on the back of the orbital process of the palatine bone and on the back of the maxilla, and enters the orbit through the inferior orbital fissure; it traverses the infra-orbital groove and canal in the floor of the orbit, and appears on the face through the infraorbital foramen.* At its termination, the nerve lies beneath the Quadratus labii superioris, and divides into branches which are distributed to the side of the nose, the lower eyelid, and the upper lip, and join with filaments of the facial nerve.

Its *branches* may be divided into four groups, according as they are given off in the cranium, in the pterygopalatine fossa, in the infraorbital canal, or on the face.

In the cranium	Middle meningeal.
In the pterygopalatine fossa	{ Zygomatic.
	{ Sphenopalatine.
	{ Posterior superior alveolar.
In the infraorbital canal .	{ Middle superior alveolar.
	{ Anterior superior alveolar.
	{ Inferior palpebral.
On the face	{ External nasal.
	{ Superior labial.

* After it enters the infraorbital canal, the nerve is frequently called the *infraorbital*.

The **middle meningeal nerve** is given off from the maxillary nerve near the semilunar ganglion; it accompanies the middle meningeal artery and supplies the dura mater.

The **zygomatic nerve** (temporomalar nerve) arises in the pterygopalatine fossa, enters the orbit by the inferior orbital fissure, and divides into two branches, zygomaticotemporal and zygomaticofacial.

The **zygomaticotemporal branch** runs along the lateral wall of the orbit in a groove in the zygomatic bone, receives a branch from the lacrimal nerve, and, passing through a canal in the zygomatic bone, enters the temporal fossa. It ascends between the temporal bone and the Temporalis muscle, pierces

FIG. 813.—The maxillary and mandibular nerves, and the submaxillary ganglion.

the temporal fascia about 2.5 cm. above the zygomatic arch, and is distributed to the skin of the side of the forehead. It communicates with the facial nerve and with the auriculotemporal branch of the mandibular nerve. As it pierces the temporal fascia, it gives off a slender twig which runs between the two layers of the fascia to the lateral angle of the orbit.

The **zygomaticofacial branch** passes along the inferolateral angle of the orbit; emerges upon the face through a foramen in the zygomatic bone, and, perforating the Orbicularis oculi, supplies the skin on the prominence of the cheek. It joins with the zygomatic branches of the facial nerve and with the inferior palpebral branches of the maxillary nerve.

The **sphenopalatine branches**, two in number; descend to the sphenopalatine ganglion.

The **posterior superior alveolar branches** arise from the maxillary nerve just before it enters the infraorbital groove; they are generally two

in number, but sometimes they arise by a single trunk. They descend on the tuberosity of the maxilla and give off several twigs to the gums and neighbouring parts of the mucous membrane of the cheek. They then enter the posterior alveolar canals on the infratemporal surface of the maxilla, and, passing forwards in the substance of the bone, communicate with the middle superior alveolar nerve, and give off branches to the lining membrane of the maxillary sinus and twigs to each molar tooth; these twigs enter the foramina at the apices of the roots of the teeth.

The **middle superior alveolar branch** is given off from the maxillary nerve in the posterior part of the infraorbital canal, and runs downwards and forwards in a canal in the lateral wall of the maxillary sinus to supply the two premolar teeth. It forms a superior dental plexus with the anterior and posterior superior alveolar branches.

The **anterior superior alveolar branch** leaves the lateral side of the maxillary nerve in the front part of the infraorbital canal, and runs in a canal in the anterior wall of the maxillary sinus. At first it curves beneath the infraorbital foramen and passes medialwards towards the nose; it then turns downwards and divides into branches which supply the incisor and canine teeth. It communicates with the middle superior alveolar branch, and gives off a *nasal branch*, which passes through a minute canal in the lateral wall of the inferior meatus, and supplies the mucous membrane of the anterior part of the inferior meatus and the floor of the nasal cavity, communicating with the nasal branches from the sphenopalatine ganglion.

The **inferior palpebral branches** ascend behind the Orbicularis oculi. They supply the skin and conjunctiva of the lower eyelid, and join with the facial and zygomaticofacial nerves at the lateral angle of the orbit.

The **external nasal branches** supply the skin of the side of the nose and of the septum mobile nasi, and join with the external nasal branch of the anterior ethmoidal nerve.

The **superior labial branches** are large and numerous: they descend behind the Quadratus labii superioris, and supply the skin of the upper lip, the mucous membrane of the mouth, and the labial glands. They are joined by branches from the facial nerve, and form with them the *infraorbital*

Sphenopalatine ganglion—The sphenopalatine ganglion (ganglion of Meckel) (fig. 814), the largest of the ganglia associated with the branches of the trigeminal nerve, is deeply placed in the pterygopalatine fossa, close to the sphenopalatine foramen. It is triangular or heart-shaped, of a reddish-grey colour, and is situated just below the maxillary nerve as it crosses the fossa. It receives sensory, motor, and sympathetic roots.

Its *sensory roots* are derived from the two sphenopalatine branches of the maxillary nerve, but most of the fibres of these branches pass directly into the palatine nerves. Its *motor root* is probably derived from the facial nerve through the greater superficial petrosal nerve, and its *sympathetic root* from the carotid plexus through the deep petrosal nerve; before entering the ganglion these two nerves join to form the nerve of the pterygoid canal.

The **greater superficial petrosal nerve** is given off from the genicular ganglion of the facial nerve; it passes through the hiatus of the facial canal, enters the cranial cavity, and runs forwards beneath the dura mater in a groove on the anterior surface of the petrous portion of the temporal bone. It then enters the cartilaginous substance which fills the foramen lacerum, and, joining with the deep petrosal branch, forms the nerve of the pterygoid canal.

The **deep petrosal nerve** is given off from the carotid plexus, and runs through the carotid canal lateral to the internal carotid artery. It then enters the cartilaginous substance which fills the foramen lacerum, and joins with the greater superficial petrosal nerve to form the nerve of the pterygoid canal.

The **nerve of the pterygoid canal** (Vidian nerve), formed by the junction of the two preceding nerves in the cartilaginous substance which fills the foramen lacerum, passes forwards through the pterygoid canal with the corresponding artery, and is joined by a small ascending *sphenoidal branch* from the otic ganglion. Finally, it enters the pterygopalatine fossa, and joins the sphenopalatine ganglion.

Branches of distribution.—These are divisible into four groups, viz. orbital, palatine, posterior superior nasal, and pharyngeal.

The *orbital branches* are two or three delicate filaments, which enter the orbit by the inferior orbital fissure, and supply the periosteum.

The *palatine nerves* are distributed to the roof of the mouth, the soft palate, the tonsil, and the lining membrane of the nasal cavity. Most of their fibres are derived from the sphenopalatine branches of the maxillary nerve. They are three in number: anterior, middle, and posterior.

The *anterior palatine nerve* descends through the pterygopalatine canal, emerges upon the hard palate through the greater palatine foramen, and passes forwards in a groove on the inferior surface of the hard palate, nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the terminal filaments of

FIG. 814.—The sphenopalatine ganglion and its branches.

the nasopalatine nerve. While in the pterygopalatine canal, it gives off *posterior inferior nasal branches*, which enter the nasal cavity through openings in the vertical part of the palatine bone, and ramify over the inferior nasal concha and middle and inferior meatuses; at its exit from the canal, a palatine branch is distributed to both surfaces of the soft palate.

The *middle palatine nerve* emerges through one of the lesser palatine foramina and supplies branches to the uvula, tonsil, and soft palate.

The *posterior palatine nerve* descends through the pterygopalatine canal, and emerges through one of the lesser palatine foramina; it supplies the uvula, tonsil, and soft palate. The middle and posterior palatine nerves form, with the tonsillar branches of the glossopharyngeal nerve, a plexus around the tonsil.

The *posterior superior nasal branches* enter the posterior part of the nasal cavity by the sphenopalatine foramen, and supply the mucous membrane covering the superior and middle nasal conchæ, the lining of the posterior ethmoidal cells, and the posterior part of the nasal septum. One branch, longer and larger than the others, is named the *nasopalatine nerve*. It crosses the roof of the nasal cavity below the orifice of the sphenoidal sinus, and then

runs obliquely downwards and forwards between the periosteum and mucous membrane of the lower part of the septum. It descends to the roof of the mouth through the incisive canal, and communicates with the corresponding nerve of the opposite side and with the anterior palatine nerve. It furnishes a few filaments to the mucous membrane of the nasal septum.

The *pharyngeal nerve*, a small branch, arises from the posterior part of the ganglion, passes through the pharyngeal canal with the pharyngeal branch of the internal maxillary artery, and is distributed to the mucous membrane of the nasal part of the pharynx, behind the auditory tube.

MANDIBULAR NERVE (figs. 813, 815)

The **mandibular nerve** (inferior maxillary nerve) supplies the teeth and gums of the mandible, the skin of the temporal region, the auricula, the lower lip, the lower part of the face, and the muscles of mastication; it also supplies the mucous membrane of the anterior two-thirds of the tongue. It is the largest division of the trigeminal nerve, and is made up of two roots: a large, sensory root proceeding from the inferior angle of the semilunar ganglion, and a small motor root (the motor part of the trigeminal) which passes beneath the ganglion, and unites with the sensory root, just after the exit of the latter from the foramen ovale. Immediately beneath the base of the skull, the nerve gives off from its medial side the *nervus spinosus* and the nerve to the *Pterygoideus internus*, and then divides into a small anterior, and a large posterior trunk.

The ***nervus spinosus*** enters the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater; the posterior branch also supplies the mucous lining of the mastoid cells; the anterior communicates with the meningeal branch of the maxillary nerve.

The **nerve to the *Pterygoideus internus*** is a slender branch which enters the deep surface of the muscle. It gives off one or two filaments to the otic ganglion.

The small anterior trunk (*nervus masticatorius*) of the mandibular nerve receives nearly the whole of the motor fibres of the trigeminal nerve, and supplies the muscles of mastication and the skin and mucous membrane of the cheek. Its branches are the masseteric, deep temporal, buccinator, and external pterygoid.

The **masseteric nerve** passes lateralwards, above the *Pterygoideus externus*, in front of the temporomandibular articulation, and behind the tendon of the *Temporalis*; it crosses the posterior part of the mandibular notch with the masseteric artery, ramifies in the deep surface of the Masseter, and gives a filament to the temporomandibular joint.

The **deep temporal nerves** are two in number, anterior and posterior. They pass above the upper border of the *Pterygoideus externus* and enter the deep surface of the *Temporalis*. The *posterior branch*, of small size, is placed at the posterior part of the temporal fossa, and sometimes arises in common with the masseteric nerve. The *anterior branch* is frequently given off from the buccinator nerve, and then ascends over the upper head of the *Pterygoideus externus*. A third or intermediate branch is often present.

The **buccinator nerve** (long buccal nerve) passes forwards between the two heads of the *Pterygoideus externus*, and downwards beneath or through the lower part of the *Temporalis*; it emerges from under the anterior border of the Masseter, ramifies on the surface of the Buccinator and unites with the buccal branches of the facial nerve. It furnishes a branch to the *Pterygoideus externus* during its passage through that muscle, and may give off the anterior deep temporal nerve. The buccinator nerve supplies the skin over the Buccinator, and the mucous membrane lining its inner surface.

The **nerve to the *Pterygoideus externus*** enters the deep surface of the muscle. It may arise from the anterior division of the mandibular nerve or in conjunction with the buccinator nerve.

The large posterior trunk of the mandibular nerve is for the most part

sensory, but receives a few filaments from the motor root. It divides into auriculotemporal, lingual, and inferior alveolar nerves.

The **auriculotemporal nerve** generally arises by two roots, which encircle the middle meningeal artery. It runs backwards beneath the Pterygoideus externus to the medial side of the neck of the mandible. It then turns upwards with the superficial temporal artery, between the auricula and condyle of the mandible, under cover of the parotid gland; escaping from beneath the gland, it ascends over the zygomatic arch, and divides into superficial temporal branches.

FIG. 815.—The Pterygoideus externus and the branches of the mandibular nerve in relation to it.

Branches of communication.—The auriculotemporal nerve communicates with the facial nerve and with the otic ganglion. The branches to the facial, usually two in number, pass forwards from behind the neck of the mandible and join the facial nerve at the posterior border of the Masseter. The filaments to the otic ganglion are derived from the roots of the auriculotemporal nerve close to their origin.

Its branches of distribution are :

Anterior auricular.

Branches to the external acoustic meatus.

Superficial temporal.

Articular.

Parotid.

The **anterior auricular branches** are usually two in number: they supply the front of the upper part of the auricula, being distributed principally to the skin covering the front of the helix and tragus.

Branches to the external acoustic meatus, two in number, enter the meatus between its bony and cartilaginous portions, and supply the skin lining it; the upper one sends a filament to the tympanic membrane.

The *articular branches* consist of one or two twigs which enter the posterior part of the temporomandibular joint.

The *parotid branches* supply the parotid gland.

The *superficial temporal branches* accompany the superficial temporal artery and its terminal branches; they supply the skin of the temporal region and communicate with the facial and zygomaticotemporal nerves.

The *lingual nerve* lies at first beneath the Pterygoideus externus, medially to and in front of the inferior alveolar nerve, to which it is often joined by a branch which may cross the internal maxillary artery. The chorda tympani branch of the facial nerve also joins it at an acute angle in this situation. The nerve then runs between the Pterygoideus internus and the ramus of the mandible, and passes obliquely to the side of the tongue over the Constrictor pharyngis superior and Styloglossus, and then between the Hyoglossus and deep part of the submaxillary gland; it finally runs across the duct of the submaxillary gland, and along the tongue to its tip, lying immediately beneath the mucous membrane.

Branches of communication.—In addition to receiving the chorda tympani and the branch from the inferior alveolar nerve, already referred to, the lingual nerve sends two or three branches to the submaxillary ganglion, and, at the anterior margin of the Hyoglossus muscle, forms two or three loops of communication with twigs of the hypoglossal nerve.

Its *branches of distribution* supply the sublingual gland, the mucous membrane of the mouth, the gums, and the mucous membrane of the anterior two-thirds of the tongue; the terminal filaments communicate, at the tip of the tongue, with the hypoglossal nerve.

The *inferior alveolar nerve* (inferior dental nerve) is the largest branch of the mandibular nerve. It descends with the inferior alveolar artery, at first beneath the Pterygoideus externus, and then between the sphenomandibular ligament and the ramus of the mandible to the mandibular foramen. It then runs in the mandibular canal, beneath the teeth, as far as the mental foramen, where it divides into an incisive and a mental branch.

The branches of the inferior alveolar nerve are the mylohyoid, dental, incisive, and mental.

The *mylohyoid nerve* is derived from the inferior alveolar just before it enters the mandibular foramen. It descends in a groove on the deep surface of the ramus of the mandible, and reaching the under surface of the Mylohyoideus supplies this muscle and the anterior belly of the Digastricus.

The *dental branches* supply the molar and premolar teeth, and the gum. They correspond in number to the roots of those teeth; each nerve entering the orifice at the point of the root, and supplying the pulp of the tooth; above the alveolar nerve they form an inferior dental plexus.

The *incisive branch* is continued onwards within the bone, and supplies the canine and incisor teeth.

The *mental nerve* emerges at the mental foramen, and divides beneath the Triangularis muscle into three branches; one descends to the skin of the chin, and two ascend to the skin and mucous membrane of the lower lip; these branches communicate freely with the facial nerve.

Two small ganglia, the otic and the submaxillary, are connected with the mandibular nerve.

Otic ganglion.—The otic ganglion (fig. 816) is a small, oval-shaped, flattened ganglion of a reddish-grey colour, situated immediately below the foramen ovale; it lies on the medial surface of the mandibular nerve, and surrounds the origin of the nerve to the Pterygoideus internus. It is in relation, *laterally*, with the trunk of the mandibular nerve at the point where the motor and sensory roots join; *medially*, with the cartilaginous part of the auditory tube, and the origin of the Tensor veli palatini; *posteriorly*, with the middle meningeal artery.

It is connected by two or three short filaments with the nerve to the Pterygoideus internus, from which it may obtain a motor, and possibly a sensory root. It communicates with the glossopharyngeal and facial nerves, through

the lesser superficial petrosal nerve continued from the tympanic plexus, and through this nerve may receive sensory fibres from the glossopharyngeal nerve and a motor root from the facial nerve; its sympathetic root consists of a filament from the sympathetic plexus surrounding the middle meningeal artery.

Branches.—A slender filament (*sphenoidal*) ascends from the ganglion to the nerve of the pterygoid canal, and a small branch connects it with the chorda tympani nerve. Two or more branches run backwards and join the roots of the auriculotemporal nerve; these branches probably carry secretory fibres from the glossopharyngeal nerve to the parotid gland. A filament is supplied to the Tensor tympani muscle, and another to the Tensor veli palatini muscle. The former passes backwards, lateral to the auditory tube; the latter arises from the ganglion, near the origin of the nerve to the Pterygoideus internus, and is directed forwards. The fibres of these nerves are, however, mainly derived from the nerve to the Pterygoideus internus.

FIG. 816.—The otic ganglion and its branches.

Submaxillary ganglion.—The submaxillary ganglion (fig. 813) is of small size and fusiform in shape. It is situated above the deep portion of the submaxillary gland, on the Hyoglossus, near the posterior border of the Mylohyoideus. It is suspended from the lingual nerve by two filaments which join the anterior and posterior parts of the ganglion. Through the posterior filament it receives a branch from the chorda tympani nerve which runs in the sheath of the lingual. The ganglion communicates with the sympathetic by filaments from the sympathetic plexus around the external maxillary (facial) artery.

Its *branches* are five or six in number; they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth, and the submaxillary gland and its duct. Fibres pass through the branch connecting the lingual nerve to the fore part of the ganglion, and are conveyed to the sublingual gland and the tongue.

Applied Anatomy.—Paralysis of the trigeminal nerve causes anaesthesia of the corresponding anterior half of the scalp, and of the face (excepting over a small area near the angle of the mandible supplied by the cervical nerves), and of the cornea and conjunctiva, and of the mucous membrane of the nose, mouth, and tongue. Taste is lost (*ageusia*) on the affected side. Paralysis and atrophy follow in the Temporalis, Masseter, and Pterygoidei, possibly also in the Tensor tympani; when the mouth is opened the mandible

is thrust over towards the paralysed side. Interference with the secretion of the tears, the nasal mucus, and the saliva, causes dryness of the corresponding mucous membranes. The sense of smell is gradually lost on the affected side from the trophic changes that follow in the nasal mucous membrane. Inflammation of the eyeball, under these circumstances known as neuromyopathic ophthalmia, is not rare, and is due to the dryness and insensitiveness of the conjunctiva; it is not a 'trophic' phenomenon, but depends on the occurrence and neglect of traumatic inflammation in the anæsthetic eye.

Trigeminal nerve reflexes.—Pains referred to various branches of the trigeminal nerve are of very frequent occurrence, and should always lead to a careful examination in order to discover a local cause. As a general rule the diffusion of pain over the various branches of the nerve is at first confined to one only of the main divisions, and the search for the causative lesion should always commence with a thorough examination of all those parts which are supplied by that division; although in severe cases pain may radiate over the branches of the other main divisions. The commonest example of this condition is the neuralgia which is so often associated with dental caries—here, although the tooth itself may not appear to be painful, the most distressing referred pains may be experienced, and these are at once relieved by treatment directed to the affected tooth.

Many other examples of trigeminal reflexes could be quoted, but it will be sufficient to mention the more common ones. Dealing with the ophthalmic nerve, severe supra-orbital pain is commonly associated with acute glaucoma or with disease of the frontal or ethmoidal air-cells. Malignant growths or empyema of the maxillary antrum, or unhealthy conditions about the inferior conchæ or the septum of the nose, are often found giving rise to 'second division' neuralgia, and should be always looked for in the absence of dental disease in the maxilla.

It is on the mandibular nerve, however, that some of the most striking reflexes are seen. It is quite common to meet with patients who complain of pain in the ear, in whom there is no sign of aural disease, and the cause is usually to be found in a carious tooth in the mandible. Moreover, with an ulcer or cancer of the tongue, often the first pain to be experienced is one which radiates to the ear and temporal fossa, over the distribution of the auriculotemporal nerve.

The trigeminal nerve is often the seat of severe neuralgia for which no local cause can be discovered; each of the three divisions has been divided, or a portion of nerve excised for this affection, usually, however, with only temporary relief. The supraorbital nerve may be exposed by making an incision 4 cm. in length along the superior orbital margin, below the eyebrow which is to be drawn upwards, the centre of the incision corresponding to the supraorbital notch. The skin and Orbicularis oculi having been divided, the nerve can be easily found emerging from the notch, and lying in some loose cellular tissue.

The infraorbital nerve has been divided at its exit by an incision on the cheek; or the infraorbital canal can be injected with absolute alcohol; or the whole nerve, together with the sphenopalatine ganglion as far back as the foramen rotundum, may be removed, but even then a return of the neuralgia in some other branches of the trigeminal nerve is the rule. Intracranial resection of the maxillary nerve between the semilunar ganglion and the foramen rotundum is an anatomical possibility.

The inferior alveolar nerve can be reached by a transverse incision over the ramus of the mandible placed so as to avoid injury to the facial nerve; the Masseter having been divided, a small trephine is applied to the ramus immediately beneath the mandibular notch, and, when the bone has been removed, the nerve is found lying on the Pterygoideus internus just as it enters the mandibular foramen, and it can here be resected. The lingual nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line be drawn from the middle of the crown of the last molar tooth to the angle of the mandible it will cross the nerve, which lies about 1.25 cm. behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. The tongue should be pulled forwards and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue, and after division of the mucous membrane can be easily seized with a hook and a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when the division is required, the operation is not practicable.

In severe cases of neuralgia of the trigeminal nerve, the semilunar ganglion has been removed in whole or in part with a considerable measure of success. Rose was the first to perform this operation; and he reached the ganglion by trephining the base of the skull in the position of the foramen ovale, after dividing the zygomatic arch, in front and behind, and turning it and the Masseter downwards, and cutting through the coronoid process of the mandible, and turning it and the Temporalis upwards. A more efficient method appears to be that known as the Krause-Hartley method. The bone forming the temporal fossa having been removed to a sufficient extent, the dura mater beneath the temporal lobe of the brain is gradually raised from the middle fossa, until the foramen spinosum, with the middle meningeal artery passing through it, is exposed. This vessel is to be ligatured in two places, and divided between the ligatures; and then by further raising the dura mater, the foramina ovale and rotundum will be exposed, with the man-

dibular and maxillary nerves passing through them. These nerves are to be clearly defined and divided. The dura mater is then to be raised from the ganglion, when the ophthalmic nerve will be exposed and can be divided, and the ganglion, by means of a little careful dissection, raised from its bed and removed. In some cases where the neuralgia has been limited to the maxillary nerve an intracranial resection of that nerve

FIG. 817.—A diagram showing the cutaneous nerve-areas of the face and scalp.

alone has been performed with great success. In other cases where the disease has not affected the ophthalmic division, resection of the lateral half of the ganglion only, with the maxillary and mandibular nerves, has been performed, thus leaving the sensory nerve supply to the cornea intact. The motor root is usually resected with the mandibular nerve, leading to complete paralysis of the muscles of mastication on that side.

ABDUCENT NERVE (fig. 812)

The abducent nerve supplies the Rectus lateralis oculi.

Its fibres arise from a small nucleus situated in the upper part of the rhomboid fossa, close to the middle line and beneath the colliculus facialis. They pass downwards and forwards through the pons, and emerge in the furrow between the lower border of the pons and the upper end of the pyramid of the medulla oblongata.

From the nucleus of the abducent nerve, fibres pass through the medial longitudinal fasciculus to the oculomotor nerve of the opposite side, along which they are carried to the Rectus medialis. The Rectus lateralis of one eye and the Rectus medialis of the other may therefore be said to receive their nerves from the same nucleus (fig. 818).

The nerve pierces the dura mater on the dorsum sellæ of the sphenoid, runs through a notch in the bone below the posterior clinoid process, and passes forwards through the cavernous sinus, on the lateral side of the internal carotid artery. It enters the orbit through the superior orbital fissure, above the ophthalmic vein, from which it is separated by a lamina of dura mater. It then passes between the two heads of the Rectus lateralis, and enters the ocular surface of that muscle.

The abducent nerve is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve.

The oculomotor, trochlear, ophthalmic, and abducent nerves bear certain relations to each other in the cavernous sinus, at the superior orbital fissure, and in the cavity of the orbit, as follows.

In the *cavernous sinus* (fig. 819), the oculomotor, trochlear, and ophthalmic nerves are placed in the lateral wall of the sinus, in the order given, from above downwards; the abducent nerve lies at the lateral side of the internal carotid artery. As these nerves pass forwards to the superior orbital fissure, the

a. Left eyeball. b. Right eyeball. 1. Rectus lateralis. 2. Rectus medialis. 3. Rhomboid fossa. 4. Nucleus of abducent nerve. 5. Nucleus of oculomotor nerve. 6. Abducent nerve. 7. Nerve to Rectus medialis arising from the nucleus of the oculomotor of the same side. 7'. Nerve to Rectus medialis arising from the nucleus of the abducent of the opposite side. 8. Decussation of the fibres of the abducent nerve to the Rectus medialis.

lacrimal on the Rectus lateralis. The superior division of the oculomotor nerve lies immediately beneath the Rectus superior, while the nasociliary nerve crosses the optic nerve to reach the medial wall of the orbit. Beneath these is the optic nerve, surrounded anteriorly by the ciliary nerves, and having the ciliary ganglion on its lateral side between it and the Rectus lateralis. Below the optic nerve are the inferior division of the oculomotor nerve, and the abducent nerve, the latter lying on the medial surface of the Rectus lateralis.

Applied Anatomy.—The abducent nerve is frequently involved in fractures of the base of the skull. The result of paralysis of this nerve is medial or convergent squint. Diplopia is also present. When injured so that its function is destroyed, there is, in addition

FIG. 819.—An oblique section through the right cavernous sinus.

oculomotor and ophthalmic divide into branches, and the abducent nerve approaches the others; so that their relative positions are considerably changed.

In the *superior orbital fissure* (fig. 820), the trochlear nerve and the frontal and lacrimal divisions of the ophthalmic nerve lie in this order from the medial to the lateral side upon the same plane; they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the Rectus lateralis. The superior division of the oculomotor nerve is the highest of these; beneath this lies the nasociliary branch of the ophthalmic nerve; then the inferior division of the oculomotor nerve; and the abducent nerve lowest of all.

In the *orbit* (fig. 811) the trochlear, frontal, and lacrimal nerves lie immediately beneath the periosteum, the trochlear nerve resting on the Obliquus superior, the frontal on the Levator palpebræ superioris, and the

to the paralysis of the *Rectus lateralis oculi*, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the *Dilatator pupillæ* muscle are conveyed through this nerve.

FACIAL NERVE (figs. 821, 823)

The facial nerve consists of a motor and a sensory part, the latter being frequently described under the name of the *nervus intermedius* of Wrisberg (fig. 821). The two parts appear at the lower border of the pons in the recess

FIG. 820.—A dissection showing the origins of the right ocular muscles, and the nerves entering the orbit through the superior orbital fissure.

between the olive and the restiform body, the motor part being the more medial; immediately to the lateral side of the sensory part is the acoustic nerve.

The motor part supplies the muscles of the face, scalp, and auricula, the *Buccinator* and *Platysma*, the *Stapedius*, the *Stylohyoideus*, and posterior belly of the *Digastricus*; it also contains some fibres which constitute the vasodilator and secretory nerves of the submaxillary and sublingual glands, and are conveyed to these glands through the *chorda tympani* nerve. The sensory part contains the fibres of taste for the anterior two-thirds of the tongue.

The motor root arises from a nucleus which lies deeply in the reticular formation of the lower part of the pons. This nucleus is situated above the nucleus ambiguus, behind the superior olivary nucleus, and medially to the spinal tract of the trigeminal nerve. From this origin the fibres pursue a curved course in the substance of the pons. They first pass backwards and medialwards, and, reaching the posterior end of the nucleus of the abducent nerve, run upwards close to the middle line beneath the *colliculus facialis*. At the anterior end of the nucleus of the abducent nerve they make a second bend, and run downwards and forwards through the pons to their point of emergence between the olive and the restiform body.

Some fibres from the nucleus of the oculomotor nerve are said to descend in the medial longitudinal fasciculus and join the motor root of the facial nerve before it leaves the pons. These fibres are said to supply the *Orbicularis*

oculi, Corrugator, and Frontalis, since these muscles have been observed to escape paralysis in lesions of the motor nucleus of the facial nerve.*

The *sensory* root arises from the genicular ganglion, which is situated on the geniculum of the facial nerve in the facial canal of the temporal bone. The cells of this ganglion are unipolar, and their single processes divide in a T-shaped manner into central and peripheral branches. The central branches leave the trunk of the facial nerve in the internal acoustic meatus, and form the sensory root of the nerve; the peripheral branches are continued into the chorda tympani and greater superficial petrosal nerves. Entering the brain at the lower border of the pons between the motor root and the acoustic nerve, the fibres of the sensory root of the facial nerve pass into the substance of the medulla oblongata

FIG. 821.—A plan of the facial nerve. The course of the sensory fibres is represented by the blue lines.

and end in the upper part of the terminal nucleus of the glossopharyngeal nerve and in the nerve-cells of the fasciculus solitarius (nucleus tractus solitarius).

From their attachments to the brain, the two roots of the facial nerve pass lateralwards and forwards with the acoustic nerve to the opening of the internal acoustic meatus. In the meatus the motor root lies in a groove on the upper and anterior surface of the acoustic nerve, the sensory root being placed between them.

At the bottom of the meatus, the facial nerve enters the facial canal, which it traverses to its termination at the stylomastoid foramen. It is at first directed lateralwards over the vestibule, and reaching the medial wall of the epitympanic recess, it bends suddenly backwards and arches downwards behind the tympanic cavity to the stylomastoid foramen. The point where it bends suddenly backwards is named the *geniculum*; it presents a reddish gangliform swelling, the *genicular ganglion*, or nucleus of the sensory root of

* See footnote, p. 790.

the nerve (fig. 822). On emerging from the stylomastoid foramen, the facial nerve runs forwards in the substance of the parotid gland, crosses the styloid process and the external carotid artery, and divides behind the ramus of the

FIG. 822.—The course and connexions of the facial nerve in the temporal bone.

mandible into branches which form a network (*parotid plexus*) and are distributed to the superficial muscles on the side of the head, face, and upper part of the neck.

The *branches of communication* of the facial nerve may be arranged as follows :

In the internal acoustic meatus

With the acoustic nerve.

With sphenopalatine ganglion by the greater superficial petrosal nerve.

At the genicular ganglion

With the otic ganglion by a branch which joins the lesser superficial petrosal nerve.

With the sympathetic plexus on the middle meningeal artery.

In the facial canal

With the auricular branch of the vagus nerve.

At its exit from the stylomastoid foramen

With the glossopharyngeal, vagus, great auricular, and auriculotemporal nerves.

Behind the ear

With the lesser occipital nerve.

On the face

With the trigeminal nerve.

In the neck

With the cutaneous cervical nerve.

In the internal acoustic meatus some minute filaments pass from the facial nerve to the acoustic nerve.

The *greater superficial petrosal nerve* arises from the genicular ganglion of the facial nerve, and consists chiefly of sensory branches which are distributed to the mucous membrane of the soft palate ; but it probably contains a few motor fibres which form the motor root of the sphenopalatine ganglion. It passes forwards through the hiatus of the facial canal, and runs in a sulcus on the anterior surface of the petrous portion of the temporal bone beneath the semilunar ganglion, to the foramen lacerum. It receives a twig from the tympanic plexus, and in the foramen is joined by the deep petrosal nerve from the sympathetic plexus on the internal carotid artery, to form the nerve of the pterygoid canal which passes forwards through the pterygoid canal and ends in the sphenopalatine ganglion. The genicular ganglion of the facial nerve is connected with the otic ganglion by a branch which joins the lesser superficial petrosal nerve, and also with the sympathetic filaments accompanying the middle meningeal artery. According to Arnold, a twig passes back from the ganglion to the acoustic nerve. Just before the facial nerve emerges from the stylomastoid foramen, it generally receives a twig from the auricular branch of the vagus.

After its exit from the stylomastoid foramen, the facial nerve sends a twig to the glossopharyngeal nerve, and communicates with the auricular branch of the vagus nerve, with the great auricular nerve of the cervical plexus, with the auriculotemporal nerve in the parotid gland, with the lesser occipital nerve behind the ear, with the terminal branches of the trigeminal nerve on the face, and with the cutaneous cervical nerve in the neck.

The *branches of distribution* (figs. 821, 823) of the facial nerve may be thus arranged :

Within the facial canal	{ Nerve to the Stapedius muscle.
	{ Chorda tympani.
At its exit from the stylo-	{ Posterior auricular.
mastoid foramen	Digastric.
	Stylohyoid.
	Temporal.
	Zygomatic.
On the face	Buccal.
	Mandibular.
	Cervical.

The nerve to the Stapedius arises opposite the pyramidal eminence on the posterior wall of the tympanic cavity (p. 987); it passes forwards through a small canal to reach the muscle.

The *chorda tympani nerve* is given off from the facial nerve about 6 mm. above the stylomastoid foramen. It runs upwards and forwards in a canal, and enters the tympanic cavity through an aperture (*iter chordæ posterioris*) on its posterior wall, close to the posterior border of the medial surface of the tympanic membrane and on a level with the upper end of the manubrium of the malleus. It traverses the tympanic cavity, between the fibrous and mucous layers of the tympanic membrane, crosses the manubrium of the malleus, and leaves the cavity through a foramen situated at the inner end of the petrotympanic fissure, and named the *iter chordæ anterioris*, or *canal of Huguier*. It runs downwards and forwards between the Pterygoidei externus and internus on the medial surface of the spina angularis of the sphenoid (which it sometimes grooves) and on the medial surface of the Pterygoideus externus, where it joins, at an acute angle, the posterior border of the lingual nerve. It contains a few efferent fibres which enter the submaxillary ganglion, and through it are distributed to the submaxillary and sublingual glands; the majority of the fibres are afferent, and are continued onwards through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds; they constitute the nerve of taste for this portion of the tongue. Before uniting with the lingual nerve the chorda tympani is joined by a small branch from the otic ganglion.

The *posterior auricular nerve* arises close to the stylomastoid foramen, and runs upwards in front of the mastoid process; here it is joined by a filament from the auricular branch of the vagus nerve, and communicates with the posterior branch of the great auricular nerve, and with the lesser occipital nerve. As it ascends between the external acoustic meatus and mastoid process it divides into an auricular and an occipital branch. The *auricular branch* supplies the Auricularis posterior and the intrinsic muscles on the cranial surface of the auricula. The *occipital branch*, the larger, passes backwards along the superior nuchal line of the occipital bone, and supplies the Occipitalis.

The *digastric branch* arises close to the stylomastoid foramen, and divides into several filaments which supply the posterior belly of the Digastricus; one of these filaments joins the glossopharyngeal nerve.

The *stylohyoid branch* frequently arises in conjunction with the digastric branch; it is long and slender, and enters the Stylohyoideus about its middle.

The *temporal branches* cross the zygomatic arch to the temporal region. They supply the Auricularis anterior and Auricularis superior, and join with the zygomaticotemporal branch of the maxillary nerve, and with the auriculo-temporal branch of the mandibular nerve. The more anterior branches supply the Frontalis, the Orbicularis oculi, and the Corrugator, and join the supra-orbital and lacrimal branches of the ophthalmic nerve.

The *zygomatic branches* run across the zygomatic bone to the lateral angle of the orbit; they supply the Orbicularis oculi, and join with filaments of the lacrimal nerve and the zygomaticofacial branch of the maxillary nerve.

The *buccal branches* pass horizontally forwards to be distributed below the orbit and around the mouth. The *superficial branches* run beneath the skin and above the superficial muscles of the face, which they supply; some are distributed to the Procerus, joining at the medial angle of the orbit with

the infratrochlear and anterior ethmoidal nerves. The *deep branches* pass beneath the Zygomaticus and the Quadratus labii superioris, supplying them and forming an *infraorbital plexus* with the superior lateral branches of the infraorbital nerve; these branches also supply the small muscles of the nose. The lower deep branches supply the Buccinator and Orbicularis oris, and join with filaments of the buccinator branch of the mandibular nerve.

The mandibular branch (ramus marginalis mandibulæ) passes forwards beneath the Platysma and Triangularis, supplies the muscles of the lower lip

FIG. 823.—The nerves of the scalp, face, and side of neck.

and chin, and communicates with the mental branch of the inferior alveolar nerve.

The *cervical branch* (ramus colli) runs forwards beneath the Platysma across the side of the neck over the suprahyoid region. It supplies the Platysma and communicates with the cervical cutaneous nerve.

Applied Anatomy.—Facial palsy is commonly unilateral, and may be either: (1) *peripheral*, from lesion of the facial nerve; (2) *nuclear*, from destruction of the facial nucleus; or (3) *central, cerebral, or supranuclear*, from injury in the brain to the fibres passing from the cortex through the internal capsule to the facial nucleus, or from injury to the face-area of the motor cortex itself. In supranuclear facial paralysis, which is usually part of a hemiplegia; it is the lower part of the face that is chiefly affected, while the forehead can be freely wrinkled on the palsied side, the eye can be closed fairly well, and

the eyeball is not rolled up under the upper lid; emotional movements of the face are much better executed than voluntary; and the electrical reactions of the muscles on the affected side are not altered. If the paralysis is due to lesion of the facial nucleus, the Orbicularis oris escapes, as the nuclear origin of the nerve to this muscle seems to be connected with that of the tongue-nerves; otherwise the symptoms are identical with those of the common peripheral facial palsy, of which several types may be distinguished according to the point in its course at which the facial nerve is injured. If the lesion occurs (a) in the pons, facial paralysis is produced as in (d) below; taste and hearing are not affected, but the abducent nerve also will be paralysed because the fibres of the facial nerve loop round its nucleus in the pons. When the nerve is paralysed (b) in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is unable, from involvement of the chorda tympani, to recognise the difference between bitters and sweets, acids and salines. The mouth is dry, because the salivary glands are not secreting; and the sense of hearing is affected from paralysis of the Stapedius. When the cause of the paralysis is (c) fracture of the base of the skull, the acoustic and petrosal nerves are usually involved. But by far the commonest cause of facial palsy is (d) exposure of the nerve to cold or injury at or after its exit from the stylomastoid foramen (Bell's paralysis). In these cases the face looks asymmetrical even when at rest, and more so in the old than in the young. The affected side of the face and forehead remains motionless when voluntary or emotional movement is attempted. The lines on the forehead are smoothed out, the eye can be shut only by hand, tears fail to enter the lacrimal puncta because they are no longer in contact with the conjunctiva, the conjunctival reflex is absent, and efforts to close the eye merely cause the eyeball to roll upwards until the cornea lies under the upper lid. The tip of the nose is drawn over towards the sound side; the nasolabial fold is partially obliterated on the affected side, and the ala nasi does not move properly on respiration. The lips remain in contact on the paralysed side, and cannot be put together for whistling; when a smile is attempted the angle of the mouth is drawn up on the unaffected side; on the affected side the lips remain nearly closed, and the mouth assumes a characteristic triangular form. During mastication food accumulates in the cheek, from paralysis of the Buccinator, and dribbles or is pushed out from between the paralysed lips. On protrusion the tongue seems to be thrust over towards the palsied side, but verification of its position by reference to the incisor teeth will show that this is not really so. The Platysma and the muscles of the auricula are paralysed; in severe cases the articulation of labials is impaired. The electrical reactions of the affected muscles are altered (reaction of degeneration), and the degree to which this alteration has taken place after a week or ten days gives a valuable guide to the prognosis. Most cases of Bell's palsy recover completely.

The facial nerve is at fault in cases of so-called 'histrionic spasm,' which consists in an almost constant and uncontrollable twitching of some or all of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient, and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear, from the root of the mastoid process to the angle of the mandible. The parotid is turned forwards and the dissection carried along the anterior border of the Sternocleidomastoideus and mastoid process, until the upper border of the posterior belly of the Digastricus is found. The nerve is parallel to this on about the level of the middle of the mastoid process. When found, the nerve must be stretched by passing a blunt hook beneath it and pulling it forwards and outwards. Too great force must not be used, for fear of permanent injury to the nerve.

ACOUSTIC NERVE

The acoustic nerve appears in the groove between the pons and medulla, behind the facial nerve and in front of the restiform body; it is distributed exclusively to the internal ear. It consists of two sets of fibres, which, although differing in their central connexions, are both concerned in the transmission of afferent impulses from the internal ear to the medulla oblongata and pons, and from there, by means of fibres which arise from collections of grey substance in these structures, to the cerebrum and cerebellum. One set of fibres forms the vestibular nerve, and arises from the cells of the vestibular ganglion situated in the internal acoustic meatus; the other set constitutes the cochlear nerve, and takes origin from the cells of the spiral ganglion of the cochlea. Both nerve-ganglia consist of bipolar nerve-cells, and from each cell a central fibre passes to the brain, and a peripheral fibre to the internal ear.

Vestibular nerve (fig. 824).—The fibres of the vestibular nerve enter the brain medially to, and on a higher level than, those of the cochlear nerve. They pass backwards through the pons between the restiform body and the spinal tract of the trigeminal nerve and divide into ascending and descending branches

ACOUSTIC NERVE

which mostly end in the vestibular nuclei. These nuclei consist of: (1) The *medial* or *chief nucleus*, situated in the area acustica of the rhomboid fossa: this nucleus is triangular on transverse section and is crossed dorsally by the *striæ medullares* (*striæ acusticæ*); the downward prolongation of the medial nucleus constitutes (2) the *descending* or *spinal nucleus*. (3) The *lateral nucleus* (nucleus of Deiters), and (4) the *superior nucleus* (nucleus of Bechterew) lie close to the restiform body, and the former contains large multipolar cells. The descending branches of the vestibular nerve end around the cells of the medial and spinal nuclei and constitute the *spinal root* of the nerve. An important strand of descending fibres, the vestibulospinal fasciculus, springs from the cells of Deiters' nucleus and runs downwards in the anterior funiculus of the medulla spinalis (p. 755); it probably conveys impulses to the motor cells of the medulla spinalis. Most of the ascending fibres end in the vestibular nuclei, but some pass directly to the roof nucleus (nucleus fastigii) and cortex of the opposite side of the cerebellum: these direct fibres are accompanied by others which originate in the cells of the vestibular nuclei. From the cells of the vestibular nuclei fibres ascend in the medial longitudinal fasciculus and end in the nuclei of the oculomotor, trochlear and abducent nerves, while others probably reach the thalamus through the lateral lemniscus.

FIG. 824.—The terminal nuclei of the vestibular nerve. (Schematic.) (Testut.)

Descending fibres of vestibular nerve. 9. Fibres passing to cerebellum. 10. Fibres going to raphe. 11. Fibres taking an oblique course. 12. Lemniscus. 13. Spinal tract of trigeminal. 14. Cerebrospinal fasciculus. 15. Raphe. 16. Fourth ventricle. 17. Restiform body. 18. Origin of striæ medullares.

Cochlear nerve (fig. 825).

—The cochlear nerve is placed laterally to the vestibular nerve. Its fibres end in two nuclei: one, the *accessory cochlear nucleus*, lies in front of the restiform body; the other, the *lateral cochlear nucleus*, on the lateral side of the restiform body.

The *striæ medullares* (*striæ acusticæ*) are the axons of cells of the lateral cochlear nucleus. They pass over the restiform body, and across the rhomboid fossa to the median sulcus. Here they dip into the substance of the pons, to end around the cells of the superior olivary nuclei of both sides. There are, however, other fibres, and these are both direct and crossed, which pass into the lateral lemniscus. The cells of the accessory cochlear nucleus give origin to fibres which run transversely in the pons and constitute the trapezium; some of these fibres end around the cells of the superior olivary nucleus or of the trapezoid nucleus of the same or opposite side, while others, crossed or uncrossed, pass directly into the lateral lemniscus.

If the further connexions of the cochlear nerve of one side, say the left, be considered, it is found that they lie lateral to the main sensory tract, the lemniscus, and are therefore termed the *lateral lemniscus*. The fibres comprising the left lateral lemniscus arise in the superior olivary and trapezoid nuclei of the same or opposite side, while others are the uninterrupted fibres already alluded to, and these are either crossed or uncrossed, the former being the axons of the cells of the right accessory and right lateral nuclei, while the latter are derived from the cells of the left nuclei. In the upper part of the lateral lemniscus there is a collection of nerve-cells, the *nucleus of the lateral lemniscus*, around the cells of which some of the fibres arborise, and from the cells of which axons originate and are continued upwards into the tract of

the lateral lemniscus. The ultimate ending of the lateral lemniscus is partly in the medial geniculate body, and partly in the inferior colliculi. From the cells of these bodies new fibres arise and ascend in the occipital part of the internal capsule to reach the posterior three-fifths of the superior temporal gyrus and the transverse temporal gyri.

The acoustic nerve contains a few efferent fibres which arise in the quadrigeminal bodies, the nucleus of the lateral lemniscus, the superior olivary, and trapezoid nuclei.

FIG. 825.—The terminal nuclei of the cochlear nerve. (Schematic.) (Testut.)

The vestibular nerve with its terminal nuclei and their efferent fibres have been suppressed. On the other hand, in order not to obscure the trapezoid body, the efferent fibres of the terminal nuclei on the right side have been resected in a considerable portion of their extent. The trapezoid body, therefore, shows only one-half of its fibres, viz. those which come from the left.

1. Vestibular nerve, divided at its entrance into the medulla oblongata. 2. Cochlear nerve. 3. Ventral or accessory cochlear nucleus. 4. Lateral cochlear nucleus. 5. Efferent fibres of accessory cochlear nucleus. 6. Efferent fibres of lateral cochlear nucleus, forming the stria medullares, with 6', their direct bundle going to the superior olivary nucleus of the same side, 6'', their decussating bundles going to the superior olivary nucleus of the opposite side. 7. Superior olivary nucleus. 8. Trapezoid body. 9. Trapezoid nucleus. 10. Ventral acoustic tract (lateral lemniscus). 11. Raphe. 12. Cerebrosplinal fasciculus. 13. Fourth ventricle. 14. Restiform body.

The acoustic nerve is soft in texture, and destitute of neurolemma. After leaving the medulla oblongata it passes forwards across the posterior border of the brachium pontis, in company with the facial nerve, from which it is partially separated by the internal auditory artery. It then enters the internal acoustic meatus with the facial nerve. At the bottom of the meatus it receives one or two filaments from the facial nerve, and divides into its two branches, *cochlear* and *vestibular*, the distribution of which will be described with the anatomy of the internal ear.

Applied Anatomy.—The acoustic nerve is frequently injured, together with the facial nerve, in fracture of the middle fossa of the base of the skull implicating the internal acoustic meatus. The nerve may be either torn across, producing permanent deafness, or it may be bruised or pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without any fracture of the bones of the skull taking place, and deafness may arise from loud explosions from dynamite, &c., probably from some lesion of this nerve, which is more liable to be injured than the other cerebral nerves on account of its structure. 'Nerve-deafness,' as contrasted with deafness due to changes in the middle ear or meatus, is suggested if (1) a sounding tuning-fork placed on the middle-line of the head is heard better (Weber's test) by the unaffected ear; or if (2) the sounding tuning-fork is heard longer when held before the affected ear (=air conduction) than when it is stood on the corresponding mastoid (=bone conduction, Rinne's test); or if (3) the sounding tuning-fork applied to the vertex or mastoid is heard less well when the air in the meatus is compressed by the use of a Siegle's speculum (Gallé's test); or

If (4) the tuning-fork placed on the mastoid is heard for a shorter time than its sound is perceptible to a normal individual (=evidence that bone conduction is diminished, Schwabach's test). It must be remembered that all these tests are liable to anomalies and exceptions, and are not applicable to old people. If, however, concordant results are yielded by the tests of Weber, Rinne, and Gellé, Bezold's 'triad of symptoms,' nerve-deafness rather than deafness due to disease of the conducting structures, is rendered highly probable.

Tinnitus aurium, or the hearing of sounds in the ear that have no objective cause outside the body, is said to be present in as many as sixty per cent. of cases of ear disease of all sorts, and is commonest in disease of the labyrinth or of the nerve. It is very variable in intensity; the worst forms are purely subjective and due to irritation of the nerve itself. The sounds heard are of the most varied nature—buzzing, hissing, whistling, rushing, bell-ringing, and so forth—and may occupy the patient's attention so completely that he is no longer able to attend to his business; he may even commit suicide in order to escape from them. In the insane, tinnitus is associated with delusions and hallucinations of hearing; cases of insanity have even been recorded in which cure was effected by the removal of cerumen impacted in the meatus and giving rise to persistent tinnitus.

GLOSSOPHARYNGEAL NERVE (figs. 826, 827, 828)

The glossopharyngeal nerve contains motor and sensory fibres, and is distributed, as its name implies, to the tongue and pharynx. It is the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces, and palatine tonsil, and the nerve of taste to the posterior part of the tongue. It is attached by three or four filaments to the upper part of the medulla oblongata, in the groove between the olive and the restiform body.

The *sensory* fibres arise from the cells of the superior and petrous ganglia, which are situated on the trunk of the nerve, and will be presently described. When traced into the medulla, some of the sensory fibres end by arborising around the cells of the upper part of a nucleus which lies beneath the ala cinerea in the lower part of the rhomboid fossa. Most of them, however, contribute to form a strand, named the *fasciculus solitarius*, which descends in the medulla oblongata. Associated with this strand are numerous nerve-cells (*nucleus tractus solitarii*) and around these cells the fibres of the fasciculus end.

The *motor* fibres spring from the cells of the *nucleus ambiguus*, which lies some distance from the surface of the rhomboid fossa in the lateral part of the medulla and is continuous below with the anterior grey column of the medulla spinalis. From this nucleus the fibres are first directed backwards towards the rhomboid fossa, and then forwards and lateralwards to join with the fibres of the sensory root.

(The nucleus ambiguus gives origin to the motor branches of the glossopharyngeal and vagus nerves, and to the cerebral part of the accessory nerve.)

From the medulla oblongata, the glossopharyngeal nerve passes lateralwards across the flocculus of the cerebellum, and leaves the skull through the central part of the jugular foramen laterally to and in front of the vagus and accessory nerves and in a separate sheath of dura mater (fig. 827). In its passage through the jugular foramen, it grooves the lower border of the petrous part of the temporal bone, and, at its exit from the skull, passes forwards between the internal jugular vein and internal carotid artery; it descends in front of the latter vessel, and beneath the styloid process and the muscles connected with it, to the lower border of the Stylopharyngeus. It then curves forwards, forming an arch on the side of the neck and lying upon the Stylopharyngeus and Constrictor pharyngis medius. Thence it passes under cover of the Hyoglossus, and is finally distributed to the palatine tonsil, the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth.

Two ganglia, the superior and the petrous, are situated on that portion of the nerve which traverses the jugular foramen (fig. 826).

The superior ganglion (jugular ganglion) is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is very small, and is usually regarded as a detached portion of the petrous ganglion.

The petrous ganglion is larger than the superior ganglion and is situated in a depression in the lower border of the petrous portion of the temporal bone.

Branches of communication.—The glossopharyngeal nerve communicates with the sympathetic trunk and with the vagus and facial nerves.

The petrous ganglion is connected by a filament with the superior cervical ganglion of the sympathetic. The branches to the vagus consist of two filaments which arise from the petrous ganglion; one passes to the auricular branch, and the other to the jugular ganglion of the vagus. The branch of communication with the facial arises from the trunk of the glossopharyngeal nerve below the petrous ganglion; it perforates the posterior belly of the Digastricus and joins the facial nerve near the stylomastoid foramen.

The *branches of distribution* of the glossopharyngeal are: tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The **tympanic nerve** (Jacobson's nerve) arises from the petrous ganglion of the glossopharyngeal nerve, and ascends to the tympanic cavity through the inferior tympanic canaliculus (p. 208). In the tympanic cavity it divides

FIG. 826.—A plan of the upper portions of the glossopharyngeal, vagus, and accessory nerves.

into branches which form the *tympanic plexus* and are contained in grooves upon the surface of the promontory. This plexus gives off: (1) the lesser superficial petrosal nerve; (2) a branch to join the greater superficial petrosal nerve; and (3) branches to the tympanic cavity, all of which will be described in connexion with the anatomy of the middle ear.

The **carotid branches** descend along the trunk of the internal carotid artery as far as its origin, communicating with the pharyngeal branch of the vagus, and with branches of the sympathetic.

The **pharyngeal branches** are three or four filaments which unite, opposite the Constrictor pharyngis medius, with the pharyngeal branches of the vagus and the laryngopharyngeal branches of the sympathetic trunk to form the *pharyngeal plexus*; branches from this plexus perforate the muscular coat of the pharynx and supply its muscles and mucous membrane.

The **muscular branch** is distributed to the Stylopharyngeus.

The **tonsillar branches** supply the palatine tonsil, and form around it a plexus with branches of the middle and posterior palatine nerves; from this plexus filaments are distributed to the soft palate and fauces.

The **lingual branches** are two in number: one supplies the papillæ vallatæ and the mucous membrane covering the base of the tongue; the other supplies the mucous membrane and follicular glands of the posterior part of the tongue, and communicates with the lingual nerve.

VAGUS NERVE (figs. 826, 827, 828)

The **vagus nerve** is composed of motor and sensory fibres, and has a more extensive course and distribution than any of the other cerebral nerves, since it passes through the neck and thorax to the abdomen.

The **vagus nerve** is attached by eight or ten filaments to the medulla oblongata in the groove between the olive and the restiform body, below the glossopharyngeal nerve. The *sensory* fibres arise from the cells of the jugular

FIG. 827.—The upper part of the medulla spinalis, and the hind- and mid-brains; exposed from behind.

ganglion and ganglion nodosum of the nerve (p. 878), and, when traced into the medulla oblongata, mostly end by arborising around the cells of the inferior part of a nucleus which lies beneath the ala cinerea in the lower part of the rhomboid fossa; a few descend in the fasciculus solitarius and end around its cells. The *motor* fibres arise from the cells of the nucleus ambiguus, already referred to in connexion with the motor root of the glossopharyngeal nerve (p. 875).

The filaments of the nerve unite, and form a flat cord which passes beneath the flocculus of the cerebellum to the jugular foramen, through which it leaves the cranium. In emerging through this opening, the vagus nerve is accompanied by and contained in the same sheath of dura mater with the accessory nerve, a septum separating them from the glossopharyngeal nerve which lies

in front (fig. 827). In this situation the vagus nerve presents a well-marked ganglionic enlargement, which is called the *jugular ganglion* (ganglion of the root); to it the accessory nerve is connected by one or two filaments. After its exit from the jugular foramen the vagus nerve is joined by the cerebral portion of the accessory nerve, and enlarges into a second gangliform swelling, called the *ganglion nodosum* (ganglion of the trunk); through this the fibres of the cerebral portion of the accessory nerve pass without interruption, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus nerve, but some of its fibres descend in the trunk of the vagus nerve, to be distributed with the recurrent nerve and probably also with the cardiac nerves.

The vagus nerve passes vertically down the neck within the carotid sheath, lying between the internal jugular vein and internal carotid artery as far as the upper border of the thyroid cartilage, and then between the same vein and the common carotid artery to the root of the neck. The further course of the nerve differs on the two sides of the body.

On the *right side*, the nerve passes across the first part of the subclavian artery, between it and the right innominate vein, and descends by the side of the trachea to the back of the root of the lung, where it spreads out in the *posterior pulmonary plexus*. From the lower part of this plexus two cords descend on the œsophagus, and divide to form, with branches from the left nerve, the *œsophageal plexus*. Below, these branches are collected into a single cord, which runs along the back of the œsophagus, enters the abdomen, and is distributed to the postero-inferior surface of the stomach, joining the left side of the celiac plexus, and sending filaments to the lienal (splenic) plexus.

On the *left side*, the nerve enters the thorax between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the left side of the arch of the aorta, and descends behind the root of the left lung, forming there the *posterior pulmonary plexus*. From this it runs along the anterior surface of the œsophagus, where it unites with branches of the right nerve in the *œsophageal plexus*, and is continued to the stomach, distributing branches over its anterosuperior surface; some of these extend over the fundus, and others along the lesser curvature. Filaments from these branches enter the lesser omentum, and join the hepatic plexus.

The *jugular ganglion* (ganglion of the root) is of a greyish colour, spherical in form, about 4 mm. in diameter. It is joined by several delicate filaments to the cerebral portion of the accessory nerve; it is connected by a twig with the petrous ganglion of the glossopharyngeal, and with the sympathetic by a filament from the superior cervical ganglion; its auricular branch gives off an ascending branch which joins the facial nerve.

The *ganglion nodosum* (ganglion of the trunk) is cylindrical in form, of a reddish colour, and 2.5 cm. in length. Passing through it is the cerebral portion of the accessory nerve, which blends with the vagus nerve below the ganglion. This ganglion is connected with the hypoglossal nerve, the superior cervical ganglion of the sympathetic trunk, and the loop between the first and second cervical nerves.

The *branches of distribution* of the vagus nerve are :

In the jugular fossa	{ Meningeal.
	{ Auricular.
	{ Pharyngeal.
In the neck	{ Superior laryngeal.
	{ Right recurrent.
	{ Superior cardiac.
	{ Inferior cardiac.
In the thorax	{ Left recurrent.
	{ Anterior bronchial.
	{ Posterior bronchial.
	{ Œsophageal.
	{ Gastric.
In the abdomen	{ Celiac.
	{ Hepatic.

The meningeal branch springs from the jugular ganglion of the vagus nerve, and is distributed to the dura mater in the posterior fossa of the skull. The auricular branch (nerve of Arnold) arises from the jugular ganglion of the vagus nerve, and is joined soon after its origin by a filament from the petrous ganglion of the glossopharyngeal; it passes behind the internal jugular vein, and enters the mastoid canaliculus on the lateral wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the facial canal about 4 mm. above the stylomastoid foramen, and here it gives off an ascending branch which joins the facial nerve. It then passes through the tympanomastoid fissure, and divides into two branches; one joins the posterior auricular nerve, the other is distributed to the skin of the back of the auricle and to the posterior part of the external acoustic meatus.

The pharyngeal branch, the principal motor nerve of the pharynx arises from the upper part of the ganglion nodosum of the vagus nerve, and consists principally of filaments from the cerebral portion of the accessory nerve. It passes across the internal carotid artery to the upper border of the Constrictor pharyngis medius, where it divides into numerous filaments which join with branches from the glossopharyngeal, sympathetic, and external laryngeal nerves to form the *pharyngeal plexus*. From the plexus, branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate, except the Tensor veli palatini. A minute filament descends and joins the hypoglossal nerve as the latter winds round the occipital artery.

The superior laryngeal nerve, larger than the preceding, arises from the middle of the ganglion nodosum of the vagus nerve and in its course receives

FIG. 828.—The course and distribution of the glossopharyngeal, vagus, and accessory nerves.

The superior laryngeal nerve, larger than the preceding, arises from the middle of the ganglion nodosum of the vagus nerve and in its course receives

a branch from the superior cervical ganglion of the sympathetic. It descends, by the side of the pharynx, behind the internal carotid artery, and divides into two branches, external and internal.

The *external branch*, the smaller, descends on the larynx, beneath the Sternothyroideus, to supply the Cricothyroideus. It gives branches to the pharyngeal plexus and to the Constrictor pharyngis inferior, and, behind the common carotid artery, communicates with the superior cardiac nerve.

The *internal branch* descends to the hyothyroid membrane, pierces it in company with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. It supplies branches to the epiglottis, the base of the tongue, and the epiglottic glands; others pass backwards, in the ary-epiglottic fold, and are distributed to the mucous membrane around the entrance to the larynx, and to the mucous membrane of the interior of the larynx as low as the vocal folds. A filament descends beneath the mucous membrane on the inner surface of the thyroid cartilage and joins the recurrent nerve.

The recurrent nerve (recurrent laryngeal nerve) differs, as to its origin and course, on the two sides of the body. On the *right* side it arises from the vagus nerve, in front of the first part of the subclavian artery; it winds from before backwards round that vessel, and ascends obliquely to the side of the trachea behind the common carotid artery, and either in front of or behind the inferior thyroid artery. On the *left* side, it arises from the vagus nerve on the left of the arch of the aorta, and winds below the aorta at the point where the ligamentum arteriosum is attached, and then ascends to the side of the trachea. The nerve on either side ascends in the groove between the trachea and œsophagus, passes under the lower border of the Constrictor pharyngis inferior, and enters the larynx behind the articulation of the inferior cornu of the thyroid with the cricoid cartilage; it is distributed to all the muscles of the larynx, excepting the Cricothyroideus. It communicates with the internal branch of the superior laryngeal nerve, and gives off a few filaments to the mucous membrane of the lower part of the larynx.

As the recurrent nerve hooks round the subclavian artery or aorta, it gives off several cardiac filaments to the deep part of the cardiac plexus. As it ascends in the neck it gives off branches, more numerous on the left than on the right side, to the mucous membrane and muscular coat of the œsophagus; branches to the mucous membrane and muscular fibres of the trachea; and some filaments to the Constrictor pharyngis inferior.

The *superior cardiac branches*, two or three in number, arise from the vagus nerve, at the upper and lower parts of the neck.

The *upper branches* are small, and join with the cardiac branches of the sympathetic trunk. They can be traced to the deep part of the cardiac plexus.

The *lower branches* arise at the root of the neck. That from the right vagus passes in front or by the side of the innominate artery, and proceeds to the deep part of the cardiac plexus; that from the left runs down across the left side of the arch of the aorta, and joins the superficial part of the cardiac plexus.

The *inferior cardiac branches*, on the right side, arise from the trunk of the vagus nerve as it lies by the side of the trachea, and from its recurrent nerve; on the left side from the recurrent nerve only. They end in the deep part of the cardiac plexus.

The *anterior bronchial branches*, two or three in number, and of small size, are distributed on the anterior surface of the root of the lung. They join with filaments from the sympathetic, and form the *anterior pulmonary plexus*.

The *posterior bronchial branches*, more numerous and larger than the anterior, are distributed on the posterior surface of the root of the lung; they are joined by filaments from the third and fourth (sometimes also from the first and second) thoracic ganglia of the sympathetic trunk, and form the *posterior pulmonary plexus*. Branches from this plexus accompany the ramifications of the bronchi through the substance of the lung.

The *œsophageal branches* are given off both above and below the bronchial branches; the lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the *œsophageal plexus*. From this plexus filaments are distributed to the œsophagus and to the back of the pericardium.

The **gastric branches** are distributed to the stomach. The right vagus forms the *posterior gastric plexus* on the postero-inferior surface of the stomach, and the left the *anterior gastric plexus* on the anterosuperior surface.

The **cœliac branches** are mainly derived from the right vagus: they join the cœliac plexus and through it supply branches to the pancreas, spleen, kidneys, suprarenal glands, and intestine.

The **hepatic branches** arise from the left vagus: they join the hepatic plexus and through it are conveyed to the liver.

Applied Anatomy.—The trunk of the vagus is rarely injured, but the functions of the nerve may be interfered with by damage to its nucleus of origin in the medulla; by thickening or growth from the meninges or bones, or aneurysm of the basilar artery, before its exit from the skull; injuries such as gunshot or punctured wounds in the neck, or injuries during such operations as ligature of the carotid artery, removal of tuberculous glands or other deep-seated tumours. The vagus may also be compressed by aneurysms of the carotid artery, and its deep origin becomes affected in bulbar paralysis. The symptoms produced by paralysis of the nerve are palpitation, with increased frequency of the pulse, constant vomiting, slowing of the respiration, and a sensation of suffocation.

'Reflexes' on the branches of the vagus are not at all uncommonly met with. The 'ear cough' is perhaps one of the commonest, where a plug of wax in the acoustic meatus may, by irritating the filaments of the auricular (Arnold's) nerve, be responsible for a persistent cough. Syringing the external acoustic meatus frequently produces cough, and, in children, vomiting is not uncommon as the result of such a procedure; moreover, in people with weak hearts, syringing the ear has been responsible for a sudden fatal syncope, by reflex irritation of the cardiac branches. Another very common example is the persistent cough which is frequently due to enlarged bronchial glands in children, the irritation of which is referred to the superior laryngeal filaments.

The anatomy of the laryngeal nerves is of importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When its trunk is pressed upon by, for instance, a goitre or an aneurysm of the upper part of the carotid, there is a peculiar dry, brassy cough. When the nerve is paralysed, there is anaesthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, as the nerve also supplies the Cricothyroideus muscle, the vocal folds cannot be made tense and the voice is deep and hoarse. Paralysis may be the result of bulbar paralysis; may be a sequel to diphtheria, when both nerves are usually involved; or it may, though less commonly, be caused by the pressure of tumours or aneurysms, when the paralysis is generally unilateral. Irritation of the recurrent nerves produces spasm of the muscles of the larynx. When both recurrent nerves are paralysed, the vocal folds are motionless, in the so-called 'cadaveric position'—that is to say, in the position in which they are found in ordinary tranquil respiration; neither closed as in phonation, nor widely open as in deep inspiratory efforts. When one recurrent nerve is paralysed, the vocal fold of the same side is motionless, while the opposite one crosses the middle line to accommodate itself to the affected one; hence phonation is possible, but the voice is altered and weak in timbre. The nerves may be paralysed in bulbar paralysis or after diphtheria, when the paralysis usually affects both sides; or they may be affected by the pressure of aneurysms of the aorta, innominate, or subclavian arteries; by mediastinal tumours; by gunnata; or by cancer of the upper part of the œsophagus, when the paralysis is often unilateral. Paralysis of the adductor muscles of the larynx on both sides is quite common, and is usually functional in nature. The voice is reduced to a whisper, but the power of coughing is preserved.

R.

ACCESSORY NERVE (figs. 826, 827, 828)

The **accessory nerve** (spinal accessory nerve) consists of two parts: a cerebral and a spinal.

The **cerebral part** is the smaller; its fibres arise from the cells of the *nucleus ambiguus* and emerge as four or five delicate rootlets from the side of the medulla oblongata, below the roots of the vagus. It runs lateralwards to the jugular foramen, where it interchanges fibres with the spinal portion or becomes united to it for a short distance; here it is also connected by one or two filaments with the jugular ganglion of the vagus. It passes through the jugular foramen, separates from the spinal portion, and is continued over the ganglion nodosum of the vagus, to the surface of which it is adherent, and is distributed principally to the pharyngeal and superior laryngeal branches of the vagus. Through the pharyngeal branch it probably supplies the *Musculus uvulæ* and *Levator veli palatini*. Some few filaments from it are

continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent nerve and probably also with the cardiac nerve.

The **spinal part** is firm in texture, and its fibres arise from the motor cells in the lateral part of the anterior column of the grey substance of the medulla spinalis as low as the fifth cervical nerve. Passing through the lateral white funiculus of the medulla spinalis, they emerge on its surface and unite to form a **trunk**, which ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed to the jugular foramen, through which it passes, lying in the same sheath of dura mater as the vagus nerve, but separated from it by a fold of the arachnoid. In the jugular foramen, it receives one or two filaments from the cerebral part of the accessory nerve, or else joins it for a short distance and then parts from it again. At its exit from the jugular foramen, it runs backwards in front of the internal jugular vein in two-thirds of the cases, and behind it in one-third (Tandler). The nerve then descends obliquely behind the Digastricus and Stylohyoideus to the upper part of the Sternocleidomastoideus; it pierces this muscle, and courses obliquely across the posterior triangle of the neck, to end in the deep surface of the Trapezius. As it traverses the Sternocleidomastoideus it gives several filaments to the muscle, and joins with branches from the second cervical nerve. In the posterior triangle it unites with the second and third cervical nerves, while beneath the Trapezius it forms a plexus with the third and fourth cervical nerves, and from this plexus fibres are distributed to the muscle.

Applied Anatomy.—The functions of the accessory nerve may be interfered with either by central changes; or at its exit from the skull, by fractures running across the jugular foramen; or in the neck, by inflamed lymph-glands, &c. The acute wry-neck in children is most commonly due to inflamed or suppurating glands, and rapidly subsides with appropriate treatment. Central irritation causes clonic spasm of the Sternocleidomastoideus and Trapezius muscles, or, as it is termed, spasmodic torticollis. In cases of this affection in which all previous palliative treatment has failed, and the spasms are so severe as to undermine the patient's health, division or excision of a portion of the accessory nerve has been resorted to. This must be done from the anterior border of the Sternocleidomastoideus. The operation consists in making an incision, 8 cm. in length, from the apex of the mastoid process along the anterior border of the muscle, which is defined and pulled backwards, so as to stretch the nerve, which is then to be sought beneath the Digastricus, about 5 cm. below the apex of the mastoid process. Unfortunately, the operation does not yield a satisfactory or permanent cure, as the spasms tend to recur after an interval, either in the same muscles or in other groups of neck muscles.

In cases where extensive dissections are undertaken for enlarged glands in the neck, it is essential that this nerve should be at once sought and isolated from the mass of inflamed glands so as to maintain its continuity.

HYPGLOSSAL NERVE (figs. 829, 830)

The **hypoglossal nerve** is the motor nerve of the tongue.

Its fibres arise from the cells of the *hypoglossal nucleus*, which is an upward prolongation of the base of the anterior column of grey substance of the medulla spinalis. This nucleus is about 2 cm. in length, and its upper part corresponds with the *trigonum hypoglossi*, or lower portion of the medial eminence of the rhomboid fossa (p. 786). The lower part of the nucleus extends downwards into the closed part of the medulla oblongata, and there lies in relation to the ventrolateral aspect of the central canal. The fibres run forwards through the medulla oblongata, and emerge in the anterolateral sulcus between the pyramid and the olive.

The rootlets of this nerve are collected into two bundles, which perforate the dura mater separately, opposite the hypoglossal canal in the occipital bone, and unite together after their passage through it; in some cases the canal is divided into two by a small bony spicule. The nerve descends almost vertically to a point corresponding with the angle of the mandible. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the vagus nerve; it then passes forwards between the vein and artery, and lower down in the neck becomes superficial below the Digastricus. The nerve then loops round the occipital artery,

and crosses the external carotid and lingual arteries below the tendon of the Digastricus. It passes beneath the tendon of the Digastricus, the Stylohyoideus, and the Mylohyoideus, lying between the last-named muscle and the Hyoglossus, and is then continued forwards in the fibres of the Genioglossus as far as the tip of the tongue, distributing branches to its muscular substance. It communicates with the vagus, sympathetic, first and second cervical, and lingual nerves.

The communications with the vagus nerve take place close to the skull, numerous filaments passing between the hypoglossal nerve and the ganglion

FIG. 829.—The hypoglossal nerve and the cervical plexus.

nodosum of the vagus nerve through the mass of connective tissue which unites the two nerves. As the nerve winds round the occipital artery it gives off a filament to the pharyngeal plexus.

Opposite the atlas the nerve receives branches from the superior cervical ganglion of the sympathetic trunk, and at the same level is joined by a filament from the loop connecting the first and second cervical nerves.

Near the anterior border of the Hyoglossus it is united to the lingual nerve by numerous filaments which ascend upon the muscle.

The branches of distribution of the hypoglossal nerve are :

Meningeal.
Descending.

Thyrohyoid.
Muscular.

Of these branches the meningeal, descending, thyrohyoid, and the muscular twig to the Geniohyoideus, are probably derived mainly from the branch

which passes from the loop between the first and second cervical to join the hypoglossal (fig. 830).

Meningeal branches.—As the hypoglossal nerve passes through the hypoglossal canal it gives off several filaments to the dura mater in the posterior fossa of the skull.

The **descending ramus**, long and slender, quits the hypoglossal nerve where the latter turns round the occipital artery, and descends in front of or within the sheath of the carotid vessels; it gives a branch to the superior belly of the Omohyoideus, and, just below the middle of the neck, joins the communicantes cervicales from the second and third cervical nerves to form a

FIG. 830.—A plan of the hypoglossal nerve.

loop, the *ansa hypoglossi*. From the convexity of this loop branches pass to supply the Sternohyoideus, the Sternothyreoides, and the inferior belly of the Omohyoideus. According to Arnold, another filament descends in front of the vessels into the thorax, and joins the cardiac and phrenic nerves.

The **thyreohyoid branch** arises from the hypoglossal nerve near the posterior border of the Hyoglossus; it runs obliquely across the greater cornu of the hyoid bone, and supplies the Thyreohyoideus muscle.

The **muscular branches** are distributed to the Styloglossus, Hyoglossus, Geniohyoideus, and Genioglossus. Numerous slender branches pass upwards into the substance of the tongue to supply its intrinsic muscles.

Applied Anatomy.—The hypoglossal nerve is an important guide in the operation of ligature of the lingual artery (p. 582). It runs forwards on the Hyoglossus just above the greater cornu of the hyoid bone, and forms the upper boundary of the triangular space in which the artery is to be sought by cutting through the fibres of the Hyoglossus. In

cases where the nerve is involved by gumma or new growth of the base of the skull, or where it has been injured on one side of the neck, or in some cases of bulbar paralysis, unilateral paralysis, together with hemiatrophy of the tongue, results; the tongue, when protruded, being directed to the paralysed side owing to the unopposed action of the Genioglossus of the opposite side. On retraction, the wasted and paralysed side of the tongue rises up higher than the other. The larynx may deviate towards the sound side on swallowing, from the unilateral paralysis of the depressors of the hyoid bone. If the paralysis is bilateral, e.g. the result of a bullet wound of the infrahyoid region, the tongue lies motionless in the mouth, taste and tactile sensibility of the organ are perfect, articulation is slow and sticky; swallowing is very difficult, and the patient has to throw his head backwards and push the bolus of food back into the pharynx with his finger before he can swallow it.

THE SPINAL NERVES

The **spinal nerves** spring from the medulla spinalis, and are transmitted through the intervertebral foramina. They number thirty-one pairs, which are grouped as follows: Cervical, 8; Thoracic, 12; Lumbar, 5; Sacral, 5; Coccygeal, 1.

The *first cervical nerve* emerges from the vertebral canal between the occipital bone and the atlas, and is therefore called the *suboccipital nerve*; the eighth issues between the seventh cervical and first thoracic vertebrae.

Nerve-roots.—Each nerve is attached to the medulla spinalis by an anterior and a posterior root, the latter being characterised by the presence of a ganglion, the *spinal ganglion*.

The **anterior root** emerges from the anterior surface of the medulla spinalis as a number of rootlets or filaments (*fila radicularia*), which coalesce to form two bundles near the intervertebral foramen.

The **posterior root** (except in the case of the first cervical nerve) is larger than the anterior; its rootlets are attached along the posterolateral furrow of the medulla spinalis and unite to form two bundles which join the spinal ganglion.

The **spinal ganglia** are collections of nerve-cells on the posterior roots of the spinal nerves. Each ganglion is oval in shape, reddish in colour, and its size bears a proportion to that of the nerve-root on which it is situated; it is bifid medially where it is joined by the two bundles of the posterior nerve-root. The ganglia are usually placed in the intervertebral foramina, immediately outside the points where the nerve-roots perforate the dura mater, but there are exceptions to this; thus the ganglia of the first and second cervical nerves lie on the vertebral arches of the atlas and epistropheus respectively, those of the sacral nerves are inside the vertebral canal, while that of the coccygeal nerve is within the sheath of dura mater.

Structure.—The ganglia consist chiefly of unipolar nerve-cells, and from these the fibres of the posterior root take origin; the single process of each cell divides after a short course into a central fibre which enters the medulla spinalis and a peripheral fibre which runs into the spinal nerve (fig. 831). Two other forms of cells are, however, present, viz.: (a) the cells of Dogiel, whose axons ramify close to the cell (type II. of Golgi) and are distributed entirely within the ganglion; and (b) multipolar cells similar to those found in the sympathetic ganglia.

The ganglia of the first pair of cervical nerves may be absent, while small *aberrant ganglia* consisting of groups of nerve-cells are sometimes found on the posterior roots of the upper cervical nerves between the spinal ganglia and the medulla spinalis.

Each nerve-root receives a covering from the pia mater, and is loosely invested by the arachnoid, the latter being prolonged as far as the points where the roots pierce the dura mater. The two roots pierce the dura mater separately, each receiving a sheath from this membrane; where the roots join to form the spinal nerve this sheath is continuous with the epineurium of the nerve.

Size and direction.—The roots of the upper four *cervical* nerves are small, those of the lower four are large. The posterior roots of the cervical nerves bear a proportion to the anterior of three to one, which is greater than in the other regions; their individual filaments are also larger than those of the anterior roots. The posterior root of the first cervical is an exception

to this, being smaller than the anterior root ; in about eight per cent. of cases it is wanting. The roots of the first and second cervical nerves are short, and run nearly horizontally to their points of exit from the vertebral canal. From the third to the eighth cervical they are directed obliquely downwards, the obliquity and length of the roots successively increasing ; the distance, however, between the level of attachment of any of these roots to the medulla spinalis and the points of exit of the corresponding nerves never exceeds the depth of one vertebra.

The roots of the *thoracic* nerves, with the exception of the first, are of small size, and the posterior roots only slightly exceed the anterior in thickness. They increase successively in length, from above downwards, and, in the lower

FIG. 831.—A scheme showing the structure of a typical spinal nerve.

1. Somatic efferent. 2. Somatic afferent. 3, 4, 5. Splanchnic efferent. 6, 7. Splanchnic afferent.

part of the thoracic region, descend in contact with the medulla spinalis for a distance equal to the height of at least two vertebræ before they emerge from the vertebral canal.

The roots of the lower *lumbar* and upper *sacral* nerves are the largest, and their individual filaments the most numerous of all the spinal nerves, while the roots of the *coccygeal* nerve are the smallest.

The roots of the lumbar, sacral, and coccygeal nerves run vertically downwards to their respective exits, and as the medulla spinalis ends near the lower border of the first lumbar vertebra it follows that the length of the successive roots must rapidly increase. As already mentioned (p. 745), the term *cauda equina* is applied to this collection of nerve-roots.

From the description given it will be seen that the largest nerve-roots, and consequently the largest spinal nerves, are attached to the cervical and lumbar swellings of the medulla spinalis ; these nerves are distributed to the upper and lower limbs.

Immediately beyond the spinal ganglion, the anterior and posterior nerve-roots unite to form the *spinal nerve* which emerges through the intervertebral foramen.

Connexions with the sympathetic trunks.—After emerging from the intervertebral foramen each spinal nerve receives a branch (*grey ramus communicans*) from the adjacent ganglion of the sympathetic trunk, while the thoracic and the first and second lumbar nerves each contribute a branch (*white ramus communicans*) to the adjoining sympathetic ganglion. The second, third, and fourth sacral nerves also supply white rami; these, however, are not connected with the ganglia of the sympathetic trunk, but run directly into the pelvic plexuses of the sympathetic.

Structure.—Each typical spinal nerve contains fibres belonging to two systems, viz. the somatic, and the sympathetic or splanchnic, as well as fibres connecting these systems with each other (fig. 831).

1. The **somatic fibres** are efferent and afferent. The *efferent* fibres originate in the cells of the anterior grey column of the medulla spinalis, and run outwards through the anterior nerve-roots to the spinal nerve. They convey impulses to the voluntary muscles, and are continuous from their origin to their peripheral distribution. The *afferent* fibres convey impressions inwards from the skin, &c., and originate in the unipolar nerve-cells of the spinal ganglia. The single processes of these cells divide into peripheral and central fibres, and the latter enter the medulla spinalis through the posterior nerve-roots.

2. The **sympathetic fibres** are also efferent and afferent. The *efferent* or *preganglionic* fibres originate in the lateral column of the medulla spinalis, and are conveyed through the anterior nerve-root and the white ramus communicans to the corresponding ganglion of the sympathetic trunk; here they may end by forming synapses around its cells, or may run through the ganglion to end in another of the ganglia of the sympathetic trunk, or in a more distally placed ganglion in one of the sympathetic plexuses. In all cases they end by forming synapses around other nerve-cells. From the cells of the ganglia of the sympathetic trunk other fibres (*postganglionic*) take origin; some of these run through the grey rami communicantes to join the spinal nerves, while others pass to the viscera, either directly or after interruption in one of the distal ganglia. The *afferent* fibres are derived partly from the unipolar cells and partly from the multipolar cells of the spinal ganglia. Their peripheral processes are carried through the white rami communicantes, and after passing through one or more sympathetic ganglia (but always without interruption in them) finally end in the tissues of the viscera. The central processes of the unipolar cells enter the medulla spinalis through the posterior nerve-root and form synapses around either somatic or sympathetic efferent neurons, thus completing reflex arcs. The dendrites of the multipolar nerve-cells form synapses around the cells of type II. (cells of Dogiel) in the spinal ganglia, and by this path the original impulse is transferred from the sympathetic to the somatic system, through which it is conveyed to the sensorium.

Divisions.—After emerging from the intervertebral foramen, each spinal nerve gives off a small *meningeal branch* which re-enters the vertebral canal through the intervertebral foramen and supplies the vertebrae and their ligaments, and the blood-vessels of the medulla spinalis and its membranes. The spinal nerve then splits into a *posterior* and an *anterior* division, each receiving fibres from both nerve-roots.

POSTERIOR DIVISIONS OF THE SPINAL NERVES

The **posterior divisions** of the spinal nerves are as a rule smaller than the anterior. They are directed backwards, and, with the exceptions of those of the first cervical, the fourth and fifth sacral, and the coccygeal, divide into medial and lateral branches for the supply of the muscles and skin (figs. 832, 833) of the posterior part of the trunk.

POSTERIOR DIVISIONS OF THE CERVICAL NERVES

The **posterior division of the first cervical or suboccipital nerve** is larger than the anterior division, and emerges above the posterior arch of the atlas and beneath the vertebral artery. It enters the suboccipital triangle and

supplies the muscles which bound this triangle, viz. the Rectus capitis posterior major, and the Obliqui superior and inferior; it gives branches also to the Rectus capitis posterior minor and the Semispinalis capitis. A filament from the branch to the Obliquus inferior joins the posterior division of the second cervical nerve.

The nerve occasionally gives off a cutaneous branch which accompanies the occipital artery to the scalp, and communicates with the greater and lesser occipital nerves.

The posterior division of the second cervical nerve is much larger

FIG. 832.—A diagram of the distribution of the cutaneous branches of the posterior divisions of the spinal nerves.

than the anterior division, and is the greatest of all the cervical posterior divisions. It emerges between the posterior arch of the atlas and the lamina of the epistropheus, below the Obliquus inferior. It supplies a twig to this muscle, receives a communicating filament from the posterior division of the first cervical, and then divides into a large medial and a small lateral branch.

The *medial* branch, called from its size and distribution, the *greater occipital nerve*, ascends obliquely between the Obliquus inferior and the Semispinalis capitis, and pierces the latter muscle and the Trapezius near their attachments to the occipital bone (fig. 832). It is then joined by a filament from the medial branch of the posterior division of the third cervical, and, ascending on the back of the head with the occipital artery, divides into branches which communicate with the lesser occipital nerve and supply the skin of the scalp as far forward as the vertex of the skull. It gives off muscular branches to the Semispinalis capitis, and occasionally a twig to the back of the auricula. The *lateral* branch supplies filaments to the Splenius, Longus capitis, and Semispinalis capitis, and is often joined by the corresponding branch of the third cervical.

The posterior division of the third cervical is intermediate in size between those of the second and fourth. Its *medial* branch runs between the Semispinalis capitis and Semispinalis cervicis, and, piercing the Splenius and Trapezius, ends in the skin. While under the Trapezius it gives off a branch called the *third occipital nerve*, which pierces the Trapezius and ends in the skin of the lower part of the back of the head (fig. 832). It lies medially to, and communicates with, the greater occipital nerve. The *lateral* branch often joins that of the second cervical.

The posterior division of the suboccipital, and the medial branches of the posterior divisions of the second and third cervical nerves are sometimes joined by communicating loops to form, the *posterior cervical plexus* (Orrueilhier).

The posterior divisions of the lower five cervical nerves divide into medial and lateral branches. The *medial* branches of the fourth and fifth run between the Semispinalis cervicis and Semispinalis capitis, and, having reached the spinous processes, pierce the Splenius and Trapezius to end in the skin (fig. 832). Sometimes the medial branch of the fifth fails to reach the

FIG. 888.—The areas of distribution of the cutaneous branches of the posterior divisions of the spinal nerves. (H. M. Johnston.)

The areas of the medial branches are in black, those of the lateral in red.

skin. The medial branches of the lowest three nerves are small, and end in the Semispinalis cervicis, Semispinalis capitis, Multifidus and Interspinales. The *lateral* branches of the lower five nerves supply the Iliocostalis cervicis, Longissimus cervicis, and Longissimus capitis.

POSTERIOR DIVISIONS OF THORACIC NERVES

The *medial* branches of the posterior divisions of the upper six thoracic nerves run between the Semispinalis dorsi and Multifidus, which they supply; they then pierce the Rhomboidei and Trapezius, and reach the skin by the sides of the spinous processes (fig. 832). The medial branches of the lower six are distributed chiefly to the Multifidus and Longissimus dorsi; occasionally they give filaments to the skin near the middle line.

The *lateral* branches increase in size from above downwards. They run through or beneath the Longissimus dorsi to the interval between it and the Iliocostalis, and supply these muscles; the lower five or six also give off cutaneous branches which pierce the Serratus posterior inferior and Latissimus dorsi in a line with the angles of the ribs (fig. 832). The lateral branches of a variable number of the upper thoracic nerves also give filaments to the skin. The lateral branch of the twelfth thoracic, after sending a filament medialwards along the iliac crest, passes downwards to the skin of the anterior part of the buttock.

The medial cutaneous branches of the posterior divisions of the thoracic nerves descend for some distance close to the spinous processes before reaching the skin, while the lateral branches travel downwards for a considerable distance—it may be as much as the breadth of four ribs—before they become superficial; the branch from the twelfth thoracic, for instance, reaches the skin only a little way above the iliac crest.*

POSTERIOR DIVISIONS OF LUMBAR NERVES

The *medial* branches of the posterior divisions of the lumbar nerves run close to the articular processes of the vertebræ and end in the Multifidus.

The *lateral* branches supply the Sacrospinalis. The upper three give off cutaneous nerves which pierce the aponeurosis of the Latissimus dorsi at the lateral border of the Sacrospinalis and cross the posterior part of the iliac crest to the skin of the buttock (fig. 832), some of their twigs running as far as the level of the greater trochanter.

POSTERIOR DIVISIONS OF SACRAL NERVES

The posterior divisions of the sacral nerves are small, and diminish in size from above downwards; they emerge, except the last, through the posterior sacral foramina. The *upper three* are covered at their points of exit by the Multifidus, and divide into medial and lateral branches.

The *medial* branches are small, and end in the Multifidus.

The *lateral* branches join with one another and with the lateral branches of the posterior divisions of the last lumbar and fourth sacral to form loops on the dorsal surface of the sacrum. From these loops branches run to the dorsal surface of the sacrotuberous ligament and form a second series of loops under the Glutæus maximus. From this second series of loops cutaneous nerves (nn. clunium medii), two or three in number, pierce the Glutæus maximus along a line drawn from the posterior superior iliac spine to the tip of the coccyx; they supply the skin over the posterior part of the buttock.

The posterior divisions of the *lower two* sacral nerves are small and lie below the Multifidus. They do not divide into medial and lateral branches, but unite with each other and with the posterior division of the coccygeal nerve to form loops on the back of the sacrum; filaments from these loops supply the skin over the coccyx.

POSTERIOR DIVISION OF COCCYGEAL NERVE

The posterior division of the coccygeal nerve does not divide into a medial and a lateral branch, but receives, as already stated, a communicating branch from the last sacral; it is distributed to the skin over the back of the coccyx.

ANTERIOR DIVISIONS OF THE SPINAL NERVES

The anterior divisions of the spinal nerves supply the anterolateral parts of the trunk, and the limbs; they are for the most part larger than the posterior divisions. In the thoracic region they run independently of one another, but in the cervical, lumbar, and sacral regions they unite near their origins to form plexuses.

* H. M. Johnston, *Journal of Anatomy and Physiology*, vol. xliii.

ANTERIOR DIVISIONS OF CERVICAL NERVES

The anterior divisions of the cervical nerves, with the exception of the first, appear between the corresponding anterior and posterior inter-transverse muscles. The anterior divisions of the *upper four* nerves unite to form the *cervical plexus*; those of the *lower four*, together with the greater part of the anterior division of the first thoracic nerve, join to form the *brachial plexus*.

Each nerve receives a grey ramus communicans, the upper four from the superior cervical ganglion, the fifth and sixth from the middle cervical ganglion, and the seventh and eighth from the inferior cervical ganglion, of the sympathetic trunk.

The anterior division of the *first cervical (suboccipital) nerve* appears above the posterior arch of the atlas vertebra, and passes forwards round the lateral side of its superior articular process, medially to the vertebral artery. It supplies a branch to the Rectus lateralis muscle, and, emerging on the medial side of that muscle, descends in front of the transverse process of the atlas and joins with the ascending branch of the second nerve.

The anterior division of the *second cervical nerve* issues between the neural arches of the atlas and epistropheus and runs forwards between the transverse processes of these two vertebrae, passing under cover of the first posterior intertransverse muscle and on the lateral side of the vertebral artery. It divides into an ascending branch which joins with the first cervical nerve, and a descending branch which unites with the ascending branch of the third cervical nerve.

CERVICAL PLEXUS

The *cervical plexus* (fig. 834) is formed by the anterior divisions of the upper four cervical nerves; each nerve, except the first, divides into an upper and a lower branch, and these unite to form three loops. The plexus is situated opposite the upper four cervical vertebrae, in front of the Levator scapulae and Scalenus medius, and beneath the Sternocleidomastoideus.

Its branches are divided into two groups, *superficial* and *deep*, and are here given in tabular form; the figures following the names indicate the spinal nerves from which the different branches take origin:

		<i>Superficial</i>		Smaller occipital	2 C.
				Great auricular	2, 3 C.
				Cutaneous cervical	2, 3 C.
				Supraclavicular	3, 4 C.
<i>Deep</i>	<i>Medial</i>	<i>Communicating</i>	{	With hypoglossal	1, 2 C.
				„ vagus	1, 2 C.
				„ sympathetic	1, 2, 3, 4 C.
				Rectus capitis lateralis	1 C.
				Rectus capitis anterior	1, 2 C.
	<i>Muscular</i>	{		Longus capitis	1, 2, 3 C.
				Communicantes cervicales	2, 3 C.
				Phrenic	3, 4, 5 C.
				Communicating with accessory	2, 3, 4 C.
				Sternocleidomastoideus	2 C.
<i>Lateral</i>	<i>Muscular</i>	{		Trapezius	3, 4 C.
				Levator scapulae	3, 4 C.
				Scalenus medius	3, 4 C.

SUPERFICIAL BRANCHES OF THE CERVICAL PLEXUS (fig. 835)

The *smaller occipital nerve* arises from the second cervical nerve, sometimes also from the third; it hooks round the accessory nerve and ascends along the posterior border of the Sternocleidomastoideus. Near the cranium it perforates the deep fascia, and is continued upwards along the side of the head behind the auricula, supplying the skin and communicating with the great

auricular and greater occipital nerves, and with the posterior auricular branch of the facial nerve. The smaller occipital nerve varies in size, and is sometimes duplicated.

It gives off an *auricular branch* which supplies the skin of the upper third of the cranial surface of the auricula, and communicates with the mastoid branch of the great auricular nerve. The auricular branch is occasionally derived from the greater occipital nerve.

FIG. 894.—A plan of the cervical plexus.

The great auricular nerve is the largest of the ascending branches. It arises from the second and third cervical nerves, winds round the posterior border of the Sternocleidomastoideus, and, after perforating the deep fascia ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into an anterior and a posterior branch.

The *anterior branch* is distributed to the skin of the face over the parotid gland, and communicates in the substance of the gland with the facial nerve.

The *posterior branch* supplies the skin over the mastoid process and on the back of the auricula, except at its upper part; a filament pierces the auricula to reach its lateral surface, where it is distributed to the lobule and lower part of the concha. The posterior branch communicates with the smaller occipital nerve, the auricular branch of the vagus nerve, and the posterior auricular branch of the facial nerve.

The cutaneous cervical nerve (transverse cervical nerve) arises from the second and third cervical nerves, turns round the posterior border of the Sternocleidomastoideus about its middle, and passes obliquely forwards behind the external jugular vein to the anterior border of the muscle. It perforates the deep cervical fascia, and divides beneath the Platysma into ascending and descending branches, which are distributed to the anterolateral parts of the neck.

FIG. 835.—The nerves of the scalp, face, and side of neck.

The *ascending branches* pass upwards to the submaxillary region, and form a plexus with the cervical branch of the facial nerve beneath the Platysma; others pierce that muscle, and are distributed to the skin of the upper and front parts of the neck.

The *descending branches* pierce the Platysma, and are distributed to the skin of the side and front of the neck, as low as the sternum.

The *supraclavicular nerves* arise by a common trunk derived from the third and fourth cervical nerves. This trunk emerges from beneath the posterior border of the Sternocleidomastoideus, descends under cover of the Platysma, and deep cervical fascia, and subdivides into anterior, middle, and posterior branches which diverge from one another and pierce the deep fascia a little above the level of the clavicle.

The *anterior supraclavicular nerves* cross obliquely over the external jugular vein and the clavicular and sternal heads of the Sternocleidomastoideus, and

supply the skin as far as the middle line. They furnish one or two filaments to the sternoclavicular joint.

The *middle supraclavicular nerves* cross the clavicle, and supply the skin over the Pectoralis major and Deltoideus, communicating with the cutaneous branches of the upper intercostal nerves.

The *posterior supraclavicular nerves* pass obliquely across the outer surface of the Trapezias and the acromion, and supply the skin of the upper and posterior parts of the shoulder.

DEEP BRANCHES OF THE CERVICAL PLEXUS. MEDIAL SERIES

The *communicating branches* consist of several filaments, which pass from the loop between the first and second cervical nerves to the vagus, hypoglossal, and sympathetic. The branch to the hypoglossal ultimately leaves that nerve as a series of branches, viz. the descending ramus, the nerve to the Thyrohyoideus and the nerve to the Geniohyoideus (p. 884). A communicating branch also passes from the fourth to the fifth cervical nerve, while each of the first four cervical nerves receives a grey ramus communicans from the superior cervical ganglion of the sympathetic.

Muscular branches supply the Longus capitis, Rectus capitis anterior, and Rectus capitis lateralis.

The *communicantes cervicales* (fig. 834) consist usually of two branches, one derived from the second, and the other from the third cervical nerve. These branches join to form the *descendens cervicalis*, which passes downwards on the lateral side of the internal jugular vein, crosses in front of the vein a little below the middle of the neck, and forms a loop (*ansa hypoglossi*) with the descending ramus of the hypoglossal in front of the sheath of the carotid vessels (p. 877). Occasionally, the loop is formed within the sheath.

The *phrenic nerve* contains motor and sensory fibres in the proportion of about two to one. It arises chiefly from the fourth cervical nerve, but receives a branch from the third and another from the fifth; the fibres from the fifth occasionally come through the nerve to the Subclavius. It is formed at the lateral border of the Scalenus anterior, and descends to the root of the neck, running obliquely across the front of that muscle, and beneath the Sternocleidomastoideus, the inferior belly of the Omohyoideus, and the transverse cervical and transverse scapular vessels. It next passes in front of the subclavian artery, between it and the subclavian vein, and, as it enters the thorax, crosses the internal mammary artery near its origin. Within the thorax, it descends nearly vertically in front of the root of the lung, and then between the pericardium and the mediastinal pleura, to the Diaphragm, where it divides into branches which pierce that muscle, and are distributed to its under surface. In the thorax it is accompanied by the pericardiophrenic branch of the internal mammary artery.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The *right nerve* is situated more deeply, and is shorter and more vertical in direction than the left. It descends in front of the Scalenus anterior which separates it from the second part of the subclavian artery. It lies laterally to the right innominate vein and superior vena cava.

The *left nerve* is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the right side. At the root of the neck it crosses the first part of the subclavian artery, and is crossed by the thoracic duct. In the superior mediastinal cavity it lies between the left common carotid and left subclavian arteries, and crosses superficially to the vagus on the left side of the arch of the aorta.

Each nerve supplies branches to the pericardium and pleura, and at the root of the neck is joined by a filament from the sympathetic, and, occasionally, by one from the ansa hypoglossi. Branches have been described as passing to the peritoneum.

From the *right nerve*, one or two filaments pass to join in a small *phrenic ganglion* with phrenic branches of the coeliac plexus; and branches from this ganglion are distributed to the falciform and coronary ligaments of the liver, the suprarenal gland, and inferior vena cava. From the *left nerve*, filaments

pass to join the phrenic branches of the coeliac plexus, but without any ganglionic enlargement; and a twig is distributed to the left suprarenal gland.

Applied Anatomy.—In addition to its supply from the phrenics, the Diaphragm receives both motor and sensory nerve-fibres from the lower seven intercostal nerves at its rim. This double sensory innervation explains the varied distribution of the referred pains that may be felt in different cases of infection or inflammation of the Diaphragm, such as may occur in pleurisy or pneumonia affecting its upper surface, on the one hand, or in peritonitis attacking its lower surface on the other. For example, if it is the more central part of the Diaphragm that becomes inflamed in a case of acute peritonitis, the patient may complain of pain and tenderness in the area of distribution of the cutaneous branches of the fourth and fifth cervical nerves, with the result that disease of the shoulder-joint or supraclavicular region is erroneously suspected, and the peritonitis is missed. Contrariwise, if the periphery of the Diaphragm chances to become infected in a patient with acute pleurisy or pneumonia, he may complain of acute pain and tenderness in the area of distribution of the cutaneous branches of the lower intercostal nerves, and may also exhibit rigidity of the underlying abdominal muscles, with the result that an acute intra-abdominal infection is erroneously diagnosed and a laparotomy is performed for the relief of a supposed appendicitis, cholecystitis, or localised peritonitis.

DEEP BRANCHES OF THE CERVICAL PLEXUS. LATERAL SERIES

Communicating branches.—The lateral series of deep branches of the cervical plexus communicates with the accessory nerve, in the substance of the Sternocleidomastoideus, in the posterior triangle, and beneath the Trapezius.

Muscular branches are distributed to the Sternocleidomastoideus, Trapezius, Levator scapulæ, and Scalenus medius.

The branch for the Sternocleidomastoideus is derived from the second cervical nerve; the Trapezius and Levator scapulæ receive branches from the third and fourth cervical nerves. The Scalenus medius receives twigs either from the third or fourth cervical nerves, or occasionally from both.

Applied Anatomy.—Pains referred to the terminal branches of the cervical plexus are not uncommon in cases of the cervical vertebrae, where pain may be felt radiating over the occipital bone, if the disease is situated high up in the vertebral column.

THE BRACHIAL PLEXUS

The brachial plexus (fig. 836) is formed by the union of the anterior divisions of the lower four cervical nerves and the greater part of the anterior division of the first thoracic nerve; the fourth cervical nerve usually gives a branch to the fifth cervical, and the first thoracic nerve frequently receives one from the second thoracic. The plexus extends from the lower part of the side of the neck to the axilla. The nerves which form it are nearly equal in size, but their mode of communication is subject to some variation. The following is, however, the most constant arrangement. The fifth and sixth cervical nerves unite at the lateral border of the Scalenus medius to form a trunk. The eighth cervical and first thoracic nerves unite behind the Scalenus anterior to form a trunk, while the seventh cervical nerve runs alone. Three trunks—upper, middle, and lower—are thus formed, and, as they pass beneath the clavicle, each splits into an *anterior* and a *posterior* division.* The anterior divisions of the upper and middle trunks unite to form a cord, which is situated on the lateral side of the second part of the axillary artery, and is called the *lateral cord or fasciculus* of the plexus. The anterior division of the lower trunk passes down on the medial side of the axillary artery, and forms the *medial cord or fasciculus* of the brachial plexus. The posterior divisions of all three trunks unite to form the *posterior cord or fasciculus* of the plexus, which is situated behind the second portion of the axillary artery.

Relations.—*In the neck*, the brachial plexus lies in the posterior triangle, being covered by the skin, Platysma, and deep fascia; it is crossed by the supraclavicular nerves, the nerve to the Subclavius, the inferior belly of the Omohyoideus, the external jugular vein, and the transverse cervical artery. It emerges between the Scalenus anterior and Scalenus medius; its upper part lies above the third part of the subclavian artery, while the trunk formed by

* The posterior division of the lower trunk is very much smaller than the others, and is frequently derived entirely from the eighth cervical nerve.

the union of the eighth cervical and first thoracic nerves is placed behind the artery; the plexus next passes behind the clavicle, the Subclavius, and the transverse scapular vessels, and lies upon the first digitation of the Serratus anterior, and the Subscapularis. In the axilla it is placed laterally to the first portion of the axillary artery; it surrounds the second part of the artery, one cord lying medially to it, one laterally to it, and one behind it; at the lower part of the axilla it gives off its terminal branches to the upper limb.

Close to their exit from the intervertebral foramina the fifth and sixth cervical nerves each receive a grey ramus commensurate with the middle cervical ganglion, and the seventh and eighth cervical similar twigs from the inferior

FIG. 836.—A plan of the brachial plexus.

cervical ganglion, and the sympathetic trunk. The first thoracic nerve receives a grey ramus from, and the first thoracic ganglion receives a white ramus to, the first thoracic ganglion of the sympathetic trunk.

Branches of the brachial plexus.—The branches of the brachial plexus may be arranged in two groups, viz. those given off above the clavicle (*supraclavicular*) and those given off below that bone (*infraclavicular*).

SUPRACLAVICULAR BRANCHES

To phrenic nerve	5 C.
Dorsal scapular	5 C.
Suprascapular	5, 6 C.
Nerve to Subclavius	5, 6 C.
Long thoracic	5, 6, 7 C.
To Longus colli and Scaleni	5, 6, 7 C.

On the Scalenus anterior the phrenic nerve is joined by a branch from the fifth cervical nerve.

The **dorsal scapular nerve** arises from the fifth cervical nerve, pierces the *Scalenus medius*, passes beneath the *Levator scapulæ*, to which it occasionally gives a twig, and runs in company with the descending branch of the **transverse scapular artery** on the anterior surface of the *Rhomboidei*: it ends by supplying these muscles.

The **suprascapular nerve** (fig. 842) is a large nerve which arises from the trunk formed by the union of the fifth and sixth cervical nerves. It runs lateralwards beneath the *Trapezius* and the *Omohyoideus*, and enters the *supraspinatous fossa* through the *suprascapular notch*, below the *superior transverse scapular ligament*; it then passes beneath the *Supraspinatus*, and curves round the lateral border of the spine of the scapula to the *infraspinatous fossa* in company with the *transverse scapular artery*. In the *supraspinatous fossa* it gives off two branches to the *Supraspinatus* muscle, and articular filaments to the shoulder-joint and the *acromioclavicular joint*; and in the *infraspinatous fossa* it gives off two branches to the *Infraspinatus* muscle, besides some filaments to the shoulder-joint and scapula.

The **nerve to the Subclavius** is a small nerve which arises from the point of junction of the fifth and sixth cervical nerves; it descends to the muscle in front of the third part of the *subclavian artery* and the lower trunk of the plexus, and is usually connected by a filament with the *phrenic nerve*.

The **long thoracic nerve** (nerve of Bell) (fig. 841) supplies the *Serratus anterior*. It usually arises by three roots from the fifth, sixth, and seventh cervical nerves, but the root from the seventh nerve may be absent. The roots from the fifth and sixth nerves pierce the *Scalenus medius*, while that from the seventh passes lateralwards in front of the muscle. The nerve descends behind the *brachial plexus* and the first part of the *axillary vessels*, resting on the outer surface of the *Serratus anterior*. It extends along the side of the thorax to the lower border of that muscle, supplying filaments to each of its digitations.

The branches for the *Longus colli* and *Scaleni* arise from the lower four cervical nerves close to their points of exit from the *intervertebral foramina*.

INFRACLAVICULAR BRANCHES

The *infraclavicular branches* are derived from the three cords of the *brachial plexus*, but their fibres may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

Lateral cord	Lateral anterior thoracic	5, 6, 7 C.
	Musculocutaneous	5, 6, 7 C.
	Lateral head of median	6, 7 C.
Medial cord	Medial anterior thoracic	
	Medial antibrachial cutaneous	
	Medial brachial cutaneous	8 C., 1 T.
	Ulnar	
	Medial head of median	
Posterior cord	Upper subscapular	5, 6 C.
	Lower subscapular	5, 6 C.
	Thoracodorsal	5, 6, 7 C.
	Axillary	5, 6 C.
	Radial	6, 7, 8 C., 1 T.

The **anterior thoracic nerves** (fig. 841) supply the *Pectoralis major* and *Pectoralis minor*.

The *lateral anterior thoracic nerve*, the larger of the two, arises, immediately below the clavicle, from the lateral cord of the *brachial plexus*, and through it from the fifth, sixth, and seventh cervical nerves. It crosses the *axillary artery* and vein, pierces the *coracoclavicular fascia*, and is distributed to the deep surface of the *Pectoralis major*. It sends a filament to join the *medial anterior thoracic* and form with it a loop in front of the first part of the *axillary artery*.

The *medial anterior thoracic nerve* receives its fibres from the eighth cervical and first thoracic nerves, and arises from the medial cord of the plexus while that cord is still on the lateral side of the *axillary artery*. It passes behind the first part of the *axillary artery*, curves forwards between the *axillary*

NEUROLOGY

artery and vein, and unites in front of the artery with a filament from the lateral anterior thoracic nerve. It then enters the deep surface of the Pectoralis minor and supplies that muscle. Two or three branches pierce the Pectoralis minor and end in the Pectoralis major.

FIG. 887.—The cutaneous nerves of the right upper extremity. Anterior

FIG. 888.—A diagram of the segmental distribution of the cutaneous nerves of the right upper extremity. Anterior view.

The subscapular nerves, two in number, spring from the posterior cord of the plexus, and through it from the fifth and sixth cervical nerves.

The *upper subscapular* nerve, the smaller, enters the upper part of the Subscapularis, and is frequently represented by two branches.

The *lower subscapular* nerve supplies the lower part of the Subscapularis, and ends in the *Teres major*; the latter muscle is sometimes supplied by a separate branch.

BRACHIAL PLEXUS

The *thoracodorsal nerve* (long subscapular nerve), a branch of the posterior cord of the plexus, derives its fibres from the fifth, sixth, and seventh cervical nerves; it follows the course of the subscapular artery, along the posterior wall of the axilla to supply the *Latissimus dorsi*, in which it may be traced as far as the lower border of the muscle.

The *axillary nerve* (circumflex nerve) (fig. 842) arises from the posterior cord of the brachial plexus, and its fibres are derived from the fifth and sixth cervical nerves. It lies at first behind the axillary artery and in front of the *Subscapularis*, and passes downwards to the lower border of that muscle. It then winds backwards, in company with the posterior humeral circumflex artery, through a quadrilateral space bounded above by the *Subscapularis* in front and the *Teres minor* behind, below by the *Teres major*, medially by the long head of the *Triceps brachii*, and laterally by the surgical neck of the humerus, and divides into an anterior and a posterior branch.

The *anterior branch* winds round the surgical neck of the humerus, beneath the *Deltoides*, with the posterior humeral circumflex vessels, as far as the anterior border of the muscle, supplying it, and giving a few small cutaneous branches, which pierce the muscle and ramify in the skin covering its lower part.

The *posterior branch* supplies the *Teres minor* and the posterior part of the *Deltoides*; upon the branch to the *Teres minor* an oval enlargement (pseudo-ganglion) usually exists. The posterior branch then pierces the deep fascia and is continued as the *lateral brachial cutaneous nerve*, which sweeps round the posterior border of the *Deltoides* and supplies the skin over the lower two-thirds of the posterior part of this muscle, as well as that covering the long head of the *Triceps brachii* (figs. 837, 839).

The trunk of the axillary nerve gives off an articular filament which enters the shoulder-joint below the *Subscapularis*.

The *musculocutaneous nerve* (fig. 841) arises from the lateral cord of the brachial plexus, opposite the lower border of the *Pectoralis minor*, its fibres being derived from the fifth, sixth, and seventh cervical nerves. It pierces the *Coracobrachialis* muscle and passes obliquely between the *Biceps brachii* and the *Brachialis*, to the lateral side of the arm; a little below the elbow it pierces the deep fascia laterally to the tendon of the *Biceps brachii* and is continued into the forearm as the *lateral antibrachial cutaneous nerve*. In its course through the arm it supplies the *Coracobrachialis*, *Biceps brachii*, and the greater part of the *Brachialis*. The branch to the *Coracobrachialis* is given off from the musculocutaneous nerve before that nerve enters the muscle; it receives its fibres from the seventh cervical nerve, and in some instances arises directly from the outer cord of the plexus. The branches to the *Biceps brachii* and *Brachialis* arise from the musculocutaneous nerve after it has pierced the *Coracobrachialis*; that supplying the *Brachialis* gives a filament to the elbow-joint. The nerve also sends a small branch to the humerus which enters the bone with the nutrient artery.

The *lateral antibrachial cutaneous nerve* (fig. 837) passes behind the cephalic vein, and descends along the radial border of the forearm to the wrist. It supplies the skin over the lateral half of the volar surface of the forearm and distributes branches which turn round the radial border of the forearm to communicate with the dorsal antibrachial cutaneous nerve and the superficial branch of the radial nerve. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the dorsal surface of the carpus. The nerve then passes downwards to the ball of the thumb, where it ends in cutaneous filaments. It communicates with the superficial branch of the radial nerve, and with the palmar cutaneous branch of the median nerve.

The musculocutaneous nerve presents frequent irregularities. It may adhere for some distance to the median nerve and then pass beneath the *Biceps brachii* instead of through the *Coracobrachialis*. Some of the fibres of the median nerve may run for some distance in the musculocutaneous nerve and then leave it to join their proper trunk; less frequently the reverse is the case, and the median nerve sends a branch to join the musculocutaneous nerve. The nerve may pass under the *Coracobrachialis* or through the *Biceps brachii*. Occasionally it gives a filament to the *Flexor teres*. It supplies the dorsal surface of the thumb when the superficial branch of the radial nerve is absent.

The medial antibrachial cutaneous nerve (internal cutaneous nerve) (fig. 841) arises from the medial cord of the brachial plexus. It derives its fibres from the eighth cervical and first thoracic nerves, and at its commencement is placed between the axillary artery and vein. It gives off, near the

FIG. 839.—The cutaneous nerves of the right upper extremity. Posterior view.

FIG. 840.—A diagram of the segmental distribution of the cutaneous nerves of the right upper extremity. Posterior view.

Median C. 5, 6, 7, 8

axilla, a filament which pierces the fascia and supplies the skin covering the Biceps brachii, almost as far as the elbow. The nerve then runs down the arm on the medial side of the brachial artery, pierces the deep fascia with the basilic vein, about the middle of the arm, and divides into a volar and an ulnar branch.

The *volar branch*, the larger, passes usually in front of, but occasionally behind, the median cubital vein (median basilic vein). It then descends on the front of the medial side of the forearm, distributing filaments to the skin as far as the wrist, and communicating with the palmar cutaneous branch of the ulnar nerve (fig. 837).

The *ulnar branch* passes obliquely downwards on the medial side of the basilic vein, in front of the medial epicondyle of the humerus, to the back of the forearm, and descends on its medial side as far as the wrist, distributing filaments to the skin. It communicates with the medial brachial cutaneous nerve, the dorsal antibrachial cutaneous branch of the radial nerve, and the dorsal branch of the ulnar nerve (fig. 839).

The *medial brachial cutaneous nerve* (lesser internal cutaneous nerve, or nerve of Wrisberg) is distributed to the skin on the medial side of the arm (fig. 835). It is the smallest branch of the brachial plexus, and, arising from the medial cord, receives its fibres from the eighth cervical and first thoracic nerves. It passes through the axilla and crosses in front of, or behind, the axillary vein. It then runs on the medial side of this vein, and communicates with the intercostobrachial nerve. It descends along the medial side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the skin of the back of the lower third of the arm, extending as far as the elbow, where some filaments are lost in the skin in front of the medial epicondyle, and others over the olecranon. It communicates with the ulnar branch of the medial antibrachial cutaneous nerve.

In some cases the medial brachial cutaneous and intercostobrachial nerves are connected by two or three filaments, which form a plexus in the axilla. In other cases the intercostobrachial nerve is large and may be reinforced by a part of the lateral cutaneous branch of the third intercostal nerve; it then takes the place of the medial brachial cutaneous nerve, receiving from the brachial plexus a communicating filament which represents the latter nerve; in a few cases this filament is wanting.

The *median nerve* (fig. 841) arises by two roots, one from the lateral and one from the medial cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front of or laterally to that vessel. Its fibres are derived from the sixth, seventh, and eighth cervical and first thoracic nerves. As it descends through the arm, it lies at first laterally to the brachial artery; about the level of the insertion of the Coracobrachialis it crosses the artery, usually in front of, but occasionally behind it, and lies on its medial side at the bend of the elbow, where it is situated behind the lacertus fibrosus (bicipital fascia), and is separated from the elbow-joint by the Brachialis. It enters the forearm between the two heads of the Pronator teres and then crosses the ulnar artery, but is separated from this vessel by the deep head of the Pronator teres. It descends beneath the Flexor digitorum sublimis, lying on the Flexor digitorum profundus, to within 5 cm. of the transverse carpal ligament; here it becomes more superficial, and is situated between the tendons of the Flexor digitorum sublimis and Flexor carpi radialis. In this situation it lies behind, and rather to the lateral side of, the tendon of the Palmaris longus, and is covered by the skin and fascia. It then passes behind the transverse carpal ligament into the palm of the hand. In its course through the forearm it is accompanied by the median artery, a branch of the volar interosseous artery.

Branches.—With the exception of the nerve to the Pronator teres, which derives its fibres from the sixth cervical nerve, and usually arises above the elbow-joint, the median nerve gives off no branches in the arm. As it passes in front of the elbow, it supplies one or two twigs to the joint.

In the forearm its branches are: muscular, volar interosseous, and palmar.

The *muscular branches* are derived from the nerve near the elbow and supply all the superficial muscles on the front of the forearm, except the Flexor carpi ulnaris.

The *volar interosseous nerve* (anterior interosseous nerve) supplies the deep muscles on the front of the forearm, except the ulnar half of the Flexor digitorum profundus. It accompanies the volar interosseous artery along the front of the antibrachial interosseous membrane, in the interval between the Flexor pollicis longus and Flexor digitorum profundus, supplying the whole

FIG. 841.—The nerves of the left upper extremity.

of the former and the lateral half of the latter muscle; it sends branches into the deep surface of the Pronator quadratus, and ends in the wrist-joint.

The *palmar branch* of the median nerve arises at the lower part of the forearm. It pierces the volar carpal ligament, and divides into a lateral and a medial branch; the lateral branch supplies the skin over the ball of the thumb, and communicates with the volar branch of the lateral antibrachial cutaneous nerve; the medial branch supplies the skin of the palm, and communicates with the palmar cutaneous branch of the ulnar nerve.

In the *palm of the hand* the median nerve is covered by the skin, the palmar aponeurosis and the superficial volar arch, and rests on the tendons of the flexor muscles. Immediately after emerging from under the transverse carpal ligament it becomes enlarged and flattened and splits into a lateral and a medial portion. The *lateral* portion of the nerve supplies a short, stout branch to certain of the muscles of the ball of the thumb, viz. the Abductor brevis, the Opponens, and the superficial head of the Flexor brevis, and then divides into three *proper volar digital nerves*; two of these supply the sides of the thumb, while the third gives a twig to the first Lumbricalis and is distributed to the radial side of the index finger. The *medial* portion of the nerve divides into two *common volar digital nerves*. The first of these gives a twig to the second Lumbricalis and runs towards the cleft between the index and middle fingers, where it divides into two proper digital nerves for the adjoining sides of these digits. The second runs towards the cleft between the middle and ring fingers, and splits into two proper digital nerves for the adjoining sides of these digits; it communicates with a branch from the ulnar nerve, and sometimes sends a twig to the third Lumbricalis.

Opposite the base of the first phalanx each proper digital nerve gives off a dorsal branch which joins the dorsal digital nerve from the superficial branch of the radial nerve, and supplies the skin on the dorsal surface of the last phalanx. At the end of the digit the digital nerve divides into two branches, one of which supplies the tip of the finger, the other ramifies around and beneath the nail. On the fingers the proper digital nerves are superficial to the corresponding arteries.

The *ulnar nerve* (fig. 841) arises from the medial cord of the brachial plexus, and derives its fibres from the eighth cervical and first thoracic nerves. It lies medially to the axillary artery, and to the brachial artery as far as the middle of the arm. Here it pierces the medial intermuscular septum, runs obliquely across the medial head of the Triceps brachii, and descends to the groove between the medial epicondyle and the olecranon, accompanied by the superior ulnar collateral artery. At the elbow, it lies in the sulcus nervi ulnaris on the back of the medial epicondyle, and enters the forearm between the two heads of the Flexor carpi ulnaris. It descends along the medial side of the forearm, lying upon the Flexor digitorum profundus; its upper half is covered by the Flexor carpi ulnaris, its lower half lies on the lateral side of the muscle, covered by the skin and fascia. In the upper third of the forearm, it is separated from the ulnar artery by a considerable interval, but in the rest of its extent lies close to the medial side of the artery. About 5 cm. above the wrist it divides into a dorsal and a volar branch.

The branches of the ulnar nerve are: articular to the elbow-joint, muscular, palmar cutaneous, dorsal, and volar.

The *articular branches* to the elbow-joint are several small filaments which arise from the nerve as it lies between the medial epicondyle and olecranon.

The *muscular branches*, two in number, arise near the elbow; one supplies the Flexor carpi ulnaris; the other, the medial half of the Flexor digitorum profundus.

The *palmar cutaneous branch* arises about the middle of the forearm, and descends on the ulnar artery, giving off some filaments to the vessel. It perforates the volar carpal ligament and ends in the skin of the palm, communicating with the palmar branch of the median nerve.

The *dorsal branch* arises about 5 cm. above the wrist; it passes backwards beneath the Flexor carpi ulnaris, perforates the deep fascia, and, running along the medial side of the back of the wrist and hand, divides into two dorsal digital branches: one supplies the medial side of the little finger; the other, the adjacent sides of the little and ring fingers. It also sends a twig to the

that given by the superficial branch of the radial nerve for the adjoining sides of the middle and ring fingers, and assists in supplying them. A branch is distributed to the metacarpal region of the hand, communicating with a twig of the superficial branch of the radial nerve (fig. 839). On the little finger the dorsal digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by dorsal branches derived from the proper volar digital branches of the ulnar nerve.

The *volar branch* crosses the transverse carpal ligament on the lateral side of the pisiform bone, medially to and a little behind the ulnar artery. It ends by dividing into a superficial and a deep branch. The *superficial branch* supplies the Palmaris brevis and the skin on the medial side of the hand, and divides into a proper volar digital branch for the medial side of the little finger, and a common volar digital branch which sends a twig to join the median nerve and then divides into two proper digital nerves for the adjoining sides of the little and ring fingers (fig. 837). The proper digital branches are distributed to the fingers in the same manner as those of the median. The *deep branch*, accompanied by the deep branch of the ulnar artery, passes between the Abductor digiti quinti and Flexor digiti quinti brevis; it then perforates the Opponens digiti quinti and follows the course of the deep volar arch beneath the flexor tendons. At its origin it supplies the three short muscles of the little finger. As it crosses the hand, it supplies all the Interossei and the third and fourth Lumbricales; it ends by supplying the Adductor pollicis and the deep portion of the Flexor pollicis brevis. It also sends articular filaments to the wrist-joint.

It has been pointed out that the medial part of the Flexor digitorum profundus is supplied by the ulnar nerve; the third and fourth Lumbricales, which are connected with the tendons of this part of the muscle, are supplied by the same nerve. In like manner the lateral part of the Flexor digitorum profundus and the first and second Lumbricales are supplied by the median nerve. The third Lumbricalis frequently receives an additional twig from the median nerve.

The *radial nerve* (musculospiral nerve) (fig. 842), the largest branch of the brachial plexus, derives its fibres from the fifth, sixth, seventh, and eighth cervical and first thoracic nerves. It descends behind the third part of the axillary artery and the upper part of the brachial artery, and in front of the tendons of the Latissimus dorsi and Teres major. It then winds with the arteria profunda brachii from the medial to the lateral side of the humerus in the sulcus nervi radialis (musculospiral groove) between the medial and lateral heads of the Triceps brachii. It pierces the lateral intermuscular septum, and passes between the Brachialis and Brachioradialis to the front of the lateral epicondyle, where it divides into a superficial and a deep branch.

The branches of the radial nerve are: muscular, cutaneous, superficial, and deep.

The *muscular branches* supply the Triceps brachii, Anconeus, Brachioradialis, Extensor carpi radialis longus, and Brachialis, and are grouped as medial, posterior, and lateral.

The medial muscular branches supply the medial and long heads of the Triceps brachii. That to the medial head is a long, slender filament, which lies close to the ulnar nerve as far as the lower third of the arm, and is therefore frequently spoken of as the *ulnar collateral nerve*.

The posterior muscular branch, of large size, arises from the part of the nerve which lies in the sulcus nervi radialis. It divides into filaments which supply the medial and lateral heads of the Triceps brachii and the Anconeus. The branch for the latter muscle is a long nerve, which descends in the substance of the medial head of the Triceps brachii, to which it gives numerous branches. It is accompanied by the middle collateral branch of the arteria profunda brachii, and crosses the back of the elbow-joint to end in the Anconeus.

The lateral muscular branches supply the Brachioradialis, Extensor carpi radialis longus, and the lateral part of the Brachialis.

The *cutaneous branches* are two in number, the posterior brachial cutaneous and the dorsal antibrachial cutaneous.

The *posterior brachial cutaneous nerve* (internal cutaneous branch of the musculospiral nerve), of small size, arises in the axilla. It passes to the medial side of the arm and supplies the skin on its dorsal surface nearly as far as the olecranon. It crosses posterior to, and communicates with, the intercostobrachial nerve.

The *dorsal antibrachial cutaneous nerve* (external cutaneous branch of musculospiral nerve) perforates the lateral head of the *Triceps brachii* at its attachment to the humerus. The *upper* and smaller branch of the nerve passes to the front of the elbow, lying close to the cephalic vein, and supplies the skin of the lateral part of the lower half of the arm (fig. 837). The *lower* branch pierces the deep fascia below the insertion of the *Deltoides*, and descends along the lateral side of the arm and elbow, and then along the back of the forearm to the wrist, supplying the skin in its course, and joining, near its termination, with dorsal branches of the lateral antibrachial cutaneous nerve (fig. 839).

The *superficial branch of the radial nerve* (radial nerve) passes along the front of the lateral side of the forearm to the commencement of its lower third. It lies at first upon the *Supinator*, laterally to the radial artery, and concealed beneath the *Brachioradialis*. In the middle third of the forearm, it lies behind the same muscle, close to the lateral side of the artery. It quits the artery about

7 cm. above the wrist, passes beneath the tendon of the *Brachioradialis*, and, piercing the deep fascia, divides into a lateral and a medial branch (fig. 839). The *lateral branch*, the smaller, supplies the skin of the radial side and ball of the thumb, joining with branches of the lateral antibrachial cutaneous nerve. The *medial branch* communicates, above the wrist, with dorsal branches of the lateral antibrachial cutaneous nerve, and, on the back of the hand, with the dorsal branch of the ulnar nerve. It then divides into four digital nerves, which are distributed as follows: the first supplies the medial side of the

FIG. 842.—The suprascapular, axillary, and radial nerves.

thumb; the second, the lateral side of the index finger; the third, the adjoining sides of the index and middle fingers; the fourth communicates with a filament from the dorsal branch of the ulnar nerve, and supplies the adjoining sides of the middle and ring fingers.*

The deep branch of the radial nerve (posterior interosseous nerve) winds to the back of the forearm round the lateral side of the radius between the two planes of fibres of the Supinator. Before reaching the back of the limb it gives a branch to the Extensor carpi radialis brevis, and another to the Supinator, and as it traverses this latter muscle it supplies additional branches to it. As it escapes from the Supinator on the back of the forearm it gives three short branches to the Extensor digitorum communis, Extensor digiti quinti proprius and Extensor carpi ulnaris, and two long branches—a medial to the Extensor pollicis longus and the Extensor indicis proprius, and a lateral which supplies the Abductor pollicis longus and ends in the Extensor pollicis brevis. The nerve, now diminished to a fine thread, descends, as the *dorsal interosseous nerve*, on the antibrachial interosseous membrane, in front of the Extensor pollicis longus, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the ligaments and articulations of the carpus.

Applied Anatomy.—The brachial plexus may be injured by falls from a height on to the side of the head and shoulder, whereby the nerves of the plexus are violently stretched; the fifth cervical nerve sustains the greatest amount of injury, and the subsequent paralysis may be confined to the muscles supplied by this nerve, viz. the Deltoides, Biceps brachii, Brachialis, and Brachioradialis, with sometimes the Supraspinatus, Infraspinatus and Supinator. The position of the limb, under such conditions, is characteristic: the arm hangs by the side and is rotated inwards; the forearm is extended and pronated. The arm cannot be raised from the side; all power of flexion of the elbow is lost, as is also supination of the forearm. This is known as Erb's paralysis, and a very similar condition is occasionally met with in new-born children, either from injury to the fifth nerve from the pressure of forceps used in effecting delivery, or from traction of the head in breech presentations. A second variety of partial palsy of the brachial plexus is known as Kumpke's paralysis. In this it is the eighth cervical and first thoracic nerves that are injured, either before or after they have joined to form the lower trunk. Atrophy follows in the intrinsic muscles of the hand, and in the flexors of the fingers and wrist; the thenar and hypothenar eminences waste and flatten; the fingers cannot be spread out or approximated, on account of the paralysis of the Interossei, and become clawed. The injury to the nerves may follow direct violence or a gunshot wound.

The brachial plexus may also be injured by violent traction on the arm, or by efforts at reducing a dislocation of the shoulder joint; and the amount of paralysis will depend upon the amount of injury to the constituent nerves. When the entire plexus is involved, the whole of the upper extremity will be paralysed and anæsthetic. In these cases the injury appears to be rather a tearing away of the roots of the nerves from the medulla spinalis than a rupture of the nerves themselves. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as 'crutch paralysis.' In these cases the radial (musculospiral) is the nerve most frequently implicated; the ulnar nerve suffers next in frequency. The median and radial nerves often suffer from 'sleep palsies,' paralysis from pressure coming on while the patient is profoundly asleep under the influence of alcohol or some narcotic.

Paralysis of the long thoracic nerve throws the Serratus anterior out of action, and may occur in porters in whom the nerve is exposed to injury as it crosses the posterior triangle of the neck. The inferior angle of the scapula is drawn towards the middle line, by the unopposed action of the Rhomboidei and Levator scapule, and tends to project backwards when the arm is held horizontally forwards. The arm cannot be raised above the horizontal unless the inferior angle of the scapula is pushed laterally for the patient.

The axillary (circumflex) nerve, on account of its course round the surgical neck of the humerus, is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint; paralysis of the Deltoides, and anæsthesia of the skin over the lower part of that muscle, result. According to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it. Paralysis of the Deltoides renders abduction of the arm to the horizontal level impossible. The associated paralysis of the Teres minor is not easily demonstrated.

Hilton gave the axillary nerve as an illustration of a law which he laid down, that 'the same trunks of nerves whose branches supply the groups of muscles moving a joint

* According to Hutchison, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx; and those to the middle and ring fingers not higher than the first phalangeal joint. — *London Hospital Gazette*, vol. iii. p. 319.

furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source.' In this way he explains the fact that an inflamed joint becomes rigid.

The *median nerve* is liable to injury in wounds of the forearm. In such cases there is loss of flexion of the second phalanges of all the fingers, and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and little fingers is effected by that portion of the *Flexor digitorum profundus* which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the *Interossei*. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. There is loss in the power of pronating the forearm; the *Brachioradialis* has the power of bringing the forearm into a position of mid-pronation, but beyond this no further pronation can be effected. The wrist can be flexed, if the hand is first adducted by the action of the *Flexor carpi ulnaris*. There is loss or impairment of sensation on the volar surfaces of the thumb, index, middle, and radial half of the ring fingers, and on the dorsal surfaces of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation would be limited to the back of the distal phalanx. In old cases the unopposed action of the *Interossei* produces backward dislocation of the interphalangeal joints. The thumb is extended and adducted to the index finger, cannot be flexed or abducted, and cannot be opposed to any one of the fingers; in consequence an 'ape-like' hand is produced. More commonly, however, the nerve is injured just above the annular ligament, when the power of flexion of the fingers and pronation of the forearm remains intact unless the *Flexor tendons* are also divided. This injury seriously interferes with the use of the hand, as, besides the wasting of the muscles of the thenar eminence, great trouble is experienced from the trophic changes which result about the skin and nails of the fingers, which are anæsthetic. In order to expose the median nerve, for the purpose of uniting the divided ends, supposing the injury to be just above the wrist, an incision should be made along the radial side of the tendon of the *Palmaris longus*, which serves as a guide to the nerve.

The *ulnar nerve* is also liable to be injured in wounds of the forearm, such injury leading to impaired power of ulnar flexion, and upon an attempt being made to flex the wrist, the hand is drawn to the radial side from paralysis of the *Flexor carpi ulnaris*; there is inability to spread out the fingers from paralysis of the *Interossei*, and for the same reason the fingers, especially the ring and little fingers, cannot be flexed at the metacarpophalangeal joints or extended at the interphalangeal joints, and the hand assumes a claw shape from the action of the opposing muscles; there is loss of power of flexion in the little and ring fingers; and there is inability to adduct the thumb. The muscles of the *hypothenar* eminence become wasted. Sensation is lost, or impaired, in the skin supplied by the nerve. In order to expose the nerve in the lower part of the forearm, an incision should be made along the radial border of the tendon of the *Flexor carpi ulnaris*, and the nerve will be found lying on the medial side of the ulnar artery. This nerve may be also affected in cases of dislocation of the shoulder or fracture of the surgical neck of the humerus. Wasting of the muscles which it supplies is not uncommonly seen where a 'cervical rib' is present; the lower end of the plexus passing between this and the first thoracic rib.

The *radial (musculospiral) nerve* is also frequently injured. In consequence of its close relationship to the humerus, it is often torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be contused against the bone by kicks or blows, or to be divided in wounds of the arm. When paralysed, the hand is flexed at the wrist and lies flaccid. This is known as *wrist-drop*. The fingers are also flexed, and on an attempt being made to extend them, the last two phalanges only will be extended, through the action of the *Lumbricales* and *Interossei*; the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm be flexed so as to allow of the action of the *Biceps brachii*. The power of extension of the forearm is lost on account of paralysis of the *Triceps brachii*, if the injury to the nerve has taken place near its origin. In cases due to pressure, sensation is hardly affected; severe injury to the nerve occasions anæsthesia over the area supplied by the superficial branch of the radial nerve, and, if the lesion be high up, on the lateral side of the upper arm and the back of the forearm (posterior brachial and dorsal anti-brachial cutaneous branches) as well. The muscles supplied by the deep branch of the radial nerve are also particularly liable to be affected in chronic lead-poisoning; here the affection is probably in the cells of the anterior column of the medulla spinalis.

The nerve is best exposed by making an incision along the medial border of the *Brachioradialis*, just above the level of the elbow-joint. The skin and superficial fascia are to be divided and the deep fascia exposed. The white line in the fascia indicating the border of the muscle is to be defined, and the deep fascia divided in this line. On raising the *Brachioradialis*, the nerve will be found lying between it and the *Brachialis*. Incisions down to the neck of the radius posteriorly or on the lateral side should never be made, as the deep branch of the radial nerve would be severed.

ANTERIOR DIVISIONS OF THORACIC NERVES

The anterior divisions of the thoracic nerves (fig. 843) are twelve in number on either side. Eleven of them are situated between the ribs, and are therefore termed *intercostal*; the twelfth lies below the last rib. Each nerve is connected with the adjoining ganglion of the sympathetic trunk by a grey and a white ramus communicans. The intercostal nerves are distributed chiefly to the parietes of the thorax and abdomen, and differ from the anterior

FIG. 843.—A diagram of the distribution of the cutaneous nerves on the front of the trunk.

divisions of the other spinal nerves, in that each pursues an independent course, i.e. there is no plexus formation. The first two nerves supply fibres to the upper limb in addition to their thoracic branches; the next four are limited in their distribution to the parietes of the thorax; the lower five supply the parietes of the thorax and abdomen; the lower seven supply both motor and sensory fibres to the Diaphragm; the twelfth is distributed to the abdominal wall and the skin of the buttock.

The first thoracic nerve.—The anterior division of the first thoracic nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters the brachial plexus (p. 895); the other and smaller branch, the *first intercostal nerve*, runs along the first intercostal space, and ends on the front of the chest as the first anterior cutaneous branch of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve as a rule gives off no lateral cutaneous branch; but sometimes it sends a small branch to communicate with the intercostobrachial. The first

thoracic nerve frequently receives a connecting twig from the second nerve ; this twig ascends over the neck of the second rib.

The upper thoracic nerves.—The anterior divisions of the second, third, fourth, fifth, and sixth thoracic nerves, and the small branch from the first thoracic, are confined to the parietes of the thorax, and are named *thoracic intercostal nerves*. They pass forwards (fig. 844) in the intercostal spaces below the intercostal vessels. At the back of the chest they lie between the pleura and the posterior intercostal membranes, but soon pierce the latter and run between the two planes of intercostal muscles as far as the middle of the rib. They then enter the substance of the *Intercostales interni*, and, running amidst their fibres as far as the costal cartilages, they gain the inner surfaces of the muscles and lie between them and the pleura. Near the sternum, they cross in front of the internal mammary artery and *Transversus thoracis* muscle,

FIG. 844.—A diagram of the course and branches of a typical intercostal nerve.

pierce the *Intercostales interni*, the anterior intercostal membranes, and the *Pectoralis major*, and are now named the *anterior cutaneous nerves of the thorax* ; they supply the skin of the mamma and of the front of the thorax ; the branch from the second nerve unites with the anterior supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the *Intercostales*, the *Subcostales*, the *Levatores costarum*, the *Serratus posterior superior*, and the *Transversus thoracis*. At the front of the thorax some of these branches cross the costal cartilages from one intercostal space to another.

Each of these intercostal nerves, except the first, gives off a *lateral cutaneous* branch, about midway between the vertebral column and the sternum. These branches pierce the *Intercostales externi*, pass between the digitations of the *Serratus anterior*, and, with the exception of the lateral cutaneous branch of the second intercostal nerve, divide into anterior and posterior branches. The *anterior branches* run forwards over the border of the *Pectoralis major* and supply twigs to the skin and the mamma ; those of the fifth and sixth nerves supply twigs to the upper digitations of the *Obliquus externus abdominis*. The *posterior branches* run backwards, and supply the skin over the scapula and *Latissimus dorsi*.

The lateral cutaneous branch of the second intercostal nerve is named the *intercostobrachial nerve* (fig. 841). It crosses the axilla to the medial side of the arm, and joins with a filament from the medial brachial cutaneous nerve. It then pierces the fascia brachii, and supplies the skin of the upper half of the medial and posterior parts of the arm, communicating with the posterior brachial cutaneous branch of the radial nerve. The size of the intercostobrachial nerve is in inverse proportion to that of the medial brachial cutaneous nerve. A second intercostobrachial nerve is frequently given off from the lateral cutaneous branch of the third intercostal; it supplies filaments to the axilla and medial side of the arm.

The lower thoracic nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh thoracic nerves are continued anteriorly from the intercostal spaces into the abdominal wall; hence they are named *thoracico-abdominal intercostal nerves*. They have the same arrangement as the upper ones as far as the anterior ends of the intercostal spaces, where they pass behind the costal cartilages, and between the *Obliquus internus* and *Transversus abdominis*, and enter the sheath of the *Rectus abdominis*. They supply the *Rectus abdominis* and end as the *anterior cutaneous branches* which supply the skin of the front of the abdomen. The lower intercostal nerves supply the *Intercostales* and abdominal muscles, and the last three send branches to the *Serratus posterior inferior*. About the middle of their course they give off *lateral cutaneous branches*; these pierce the *Intercostales externi* and the *Obliquus externus abdominis*, in the same line as the lateral cutaneous branches of the upper thoracic nerves, and divide into anterior and posterior branches, which are distributed to the skin of the abdomen and back respectively; the anterior branches supply twigs to the digitations of the *Obliquus externus abdominis*, and extend downwards and forwards nearly as far as the margin of the *Rectus abdominis*; the posterior branches pass backwards to supply the skin over the *Latissimus dorsi*.

The anterior division of the twelfth thoracic nerve is larger than the others, and often gives a communicating branch to the first lumbar nerve. It accompanies the subcostal artery along the lower border of the twelfth rib, and passes under the lateral lumbocostal arch. It then runs in front of the *Quadratus lumborum*, perforates the posterior aponeurosis of the *Transversus*, and passes forwards between it and the *Obliquus internus*, to be distributed in the same manner as the lower intercostal nerves. It communicates with the iliohypogastric nerve of the lumbar plexus, and gives a branch to the *Pyramidalis*. The *lateral cutaneous branch* of the twelfth thoracic nerve is large, and does not divide into an anterior and a posterior branch. It pierces the *Obliquus internus* and *Obliquus externus*, gives a twig to the lowest slip of the latter muscle, descends over the iliac crest in front of the lateral cutaneous branch of the iliohypogastric nerve (fig. 851), and is distributed to the skin of the front part of the gluteal region, some of its filaments reaching as low as the greater trochanter.

Applied Anatomy.—The lower seven thoracic nerves and the iliohypogastric branch of the first lumbar nerve supply the skin of the abdominal wall. They run downwards and forwards fairly equidistant from each other. The sixth and seventh supply the skin over the 'pit of the stomach'; the eighth corresponds to about the position of the middle tendinous inscription of the *Rectus abdominis*; the tenth to the umbilicus; the iliohypogastric supplies the skin over the os pubis and subcutaneous inguinal ring. In many diseases affecting the nerve-trunks at or near their origins, the pain is referred to their peripheral terminations. Thus, in Pott's disease of the vertebræ, children often suffer from pain in the abdomen. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen, and in these cases the situation of the sense of constriction may serve to localise the disease in the vertebral column. In other cases where the bone disease is more extensive and two or more nerves are involved, a more general, diffused pain in the abdomen is felt.

Again, it must be borne in mind that the nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall. Hence, any irritation applied to the peripheral ends of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction;

whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more rapid response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

The nerves supplying the abdominal muscles and skin, derived from the lower intercostal nerves, are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in laceration of the abdominal viscera and in acute peritonitis, the muscles of the belly wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

ANTERIOR DIVISIONS OF LUMBAR NERVES

The anterior divisions of the lumbar nerves increase in size from the first to the last. They are joined, near their origins, by *grey rami communicantes* from the lumbar ganglia of the sympathetic trunk. These rami consist of long, slender branches which accompany the lumbar arteries round the sides of the vertebral bodies, beneath the Psoas major. Their arrangement is somewhat irregular: one ganglion may give rami to two lumbar nerves, or one lumbar nerve may receive rami from two ganglia. The first and second, and sometimes the third and fourth, lumbar nerves are each connected with the lumbar part of the sympathetic trunk by a *white ramus communicans*.

The nerves pass obliquely outwards behind the Psoas major, or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The first three and the greater part of the fourth form the *lumbar plexus*. The smaller part of the fourth joins with the fifth to form the *lumbosacral trunk*, which assists in the formation of the sacral plexus. The fourth nerve is named the *nervus furcalis*, from the fact that it is subdivided between the two plexuses.*

LUMBAR PLEXUS

The lumbar plexus (fig. 845) is situated in the posterior part of the Psoas major, in front of the transverse processes of the lumbar vertebrae; it is formed by the anterior divisions of the first three, and the greater part of the anterior division of the fourth, lumbar nerves; the first lumbar receives a branch from the last thoracic nerve.

The mode in which it is arranged varies in different subjects, but the usual condition is the following. The first lumbar nerve, supplemented by a twig from the last thoracic, splits into an upper and a lower branch; the upper, larger branch divides into the *iliohypogastric* and *ilio-inguinal* nerves; the lower, smaller branch unites with a branch of the second lumbar to form the *genitofemoral nerve*. The remainder of the second nerve, and the third and fourth nerves, divide into ventral and dorsal divisions. The ventral division of the second unites with the ventral divisions of the third and fourth nerves to form the *obturator nerve*. The dorsal divisions of the second and third nerves each divide into a smaller and a larger branch, the smaller branches uniting to form the *lateral femoral cutaneous nerve*, and the larger branches joining with the dorsal division of the fourth nerve to form the *femoral nerve*. The accessory obturator, when it exists, arises from the ventral divisions of the third and fourth nerves.

* In most cases the fourth lumbar is the *nervus furcalis*; but this arrangement is frequently departed from. The third is occasionally the lowest nerve which enters the lumbar plexus, giving at the same time some fibres to the sacral plexus, and thus forming the *nervus furcalis*; or both the third and fourth may be furcal nerves. When this occurs, the plexus is termed *high or propped*. More frequently the fifth nerve is divided between the lumbar and sacral plexuses, and constitutes the *nervus furcalis*; and when this takes place, the plexus is distinguished as a *low or pulled* plexus. These variations necessarily produce corresponding modifications in the sacral plexus.

The branches of the lumbar plexus may therefore be arranged as follows :

Iliohypogastric	1 L.
Ilio-inguinal	1 L.
Genitofemoral	1, 2 L.
		Dorsal divisions.
Lateral femoral cutaneous	2, 3 L.
Femoral	2, 3, 4 L.
		Ventral divisions.
Obturator	2, 3, 4 L.
Accessory obturator	3, 4 L.

The iliohypogastric nerve arises from the first lumbar nerve. It emerges from the upper part of the lateral border of the Psoas major, and crosses obliquely in front of the Quadratus lumborum to the iliac crest. It then

FIG. 845.—A plan of the lumbar plexus.

perforates the posterior part of the Transversus abdominis, and divides between that muscle and the Obliquus internus abdominis into a lateral and an anterior cutaneous branch.

The *lateral cutaneous branch* pierces the Obliquus internus and Obliquus externus immediately above the iliac crest at a point about 5 cm. behind the anterior superior iliac spine: it is distributed to the skin of the anterior part of the glutæal region, behind the lateral cutaneous branch of the last thoracic nerve (fig. 851).

The *anterior cutaneous branch* (fig. 843) runs between the Obliquus internus and Transversus, supplying twigs to both muscles. It then pierces the Obliquus internus at a point about 2 cm. on the medial side of the anterior superior iliac spine, perforates the aponeurosis of the Obliquus externus about 3 cm. above the subcutaneous inguinal ring, and is distributed to the skin of the abdomen above the os pubis.

The iliohypogastric nerve communicates with the last thoracic and ilio-inguinal nerves.

The ilio-inguinal nerve, smaller than the iliohypogastric nerve, arises with it from the first lumbar nerve. It emerges from the lateral border of the Psoas major just below the iliohypogastric nerve, and, passing obliquely across the Quadratus lumborum and Iliacus, perforates the Transversus abdominis, near the anterior part of the iliac crest, and communicates with the iliohypogastric nerve. It then pierces the Obliquus internus, distributing filaments to it, and, accompanying the spermatic cord through the subcutaneous inguinal ring, is distributed to the skin of the upper and medial part of the thigh, to the skin over the root of the penis and upper part of the scrotum in the male, and to the skin covering the mons pubis (mons Veneris) and labium majus in the female. The size of this nerve is in inverse proportion to that of the iliohypogastric. Occasionally it is very small, and ends by joining the iliohypogastric nerve; in such cases, a branch from the iliohypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent.

The genitofemoral nerve (genitocrural nerve) arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas major, and emerges near its medial border, opposite the fibrocartilage between the third and fourth lumbar vertebræ; it then descends on the surface of the Psoas major, under cover of the peritoneum, and divides into the external spermatic and lumbo-inguinal nerves. The genitofemoral nerve frequently divides close to its origin, and the external spermatic and lumbo-inguinal nerves then emerge separately through the Psoas major.

The external spermatic nerve (genital branch of genitocrural) passes laterally on the Psoas major, and pierces the fascia transversalis, or passes through the abdominal inguinal ring; it then descends behind the spermatic cord, supplies the Cremaster, and gives a few filaments to the skin of the scrotum. In the female, it accompanies the round ligament of the uterus and ends in the skin of the mons pubis and labium majus.

The lumbo-inguinal nerve (crural branch of genitocrural) descends on the external iliac artery, sending a few filaments round it, and, passing beneath the inguinal ligament, enters the sheath of the femoral vessels, lying superficially and laterally to the femoral artery. It pierces the anterior layer of the sheath of the vessels and the fascia lata, and supplies a limited area of the skin on the anterior surface of the upper part of the thigh (fig. 846). On the front of the thigh it communicates with the anterior cutaneous branches of the femoral nerve. As the nerve runs beneath the inguinal ligament it gives a few twigs to the femoral artery.

The lateral femoral cutaneous nerve (external cutaneous nerve) arises from the dorsal divisions of the second and third lumbar nerves. It emerges from the lateral border of the Psoas major, and crosses the Iliacus obliquely, towards the anterior superior iliac spine. It then passes under the inguinal ligament and over the Sartorius muscle into the thigh, where it divides into an anterior and a posterior branch (fig. 846).

The anterior branch becomes superficial about 10 cm. below the inguinal ligament, and is distributed to the skin of the anterior and lateral parts of the thigh, as far as the knee. Its terminal filaments frequently communicate with the anterior cutaneous branches of the femoral nerve, and with the infrapatellar branch of the saphenous nerve, forming with them the *patellar plexus*.

The posterior branch pierces the fascia lata at a higher level than the anterior branch, and subdivides into filaments which pass backwards to supply the skin on the lateral surface of the limb, from the level of the greater trochanter to about the middle of the thigh.

The obturator nerve arises from the ventral divisions of the second, third, and fourth lumbar nerves; the branch from the third is the largest, while that from the second is often very small. It descends through the fibres of the Psoas major, and emerges from its medial border at the brim of the pelvis; it then passes behind the common iliac vessels, and on the lateral side of the hypogastric vessels, and runs along the lateral wall of the lesser pelvis, above and in front of the obturator vessels, to the upper part of the obturator foramen. Here it enters the thigh, and divides into an anterior and a posterior

branch, which are separated at first by a few fibres of the Obturator externus, and lower down by the Adductor brevis.

FIG. 846.—The cutaneous nerves of the right lower extremity. Front view.

FIG. 847.—A diagram of the segmental distribution of the cutaneous nerves of the right lower extremity. Front view.

The anterior branch (fig. 848) leaves the pelvis in front of the Obturator externus and descends in front of the Adductor brevis, and behind the Pectineus and Adductor longus ; at the lower border of the latter muscle it communicates

with the anterior cutaneous and saphenous branches of the femoral nerve, forming a kind of plexus, which it is finally distributed. Near the obturator foramen the nerve gives off an articular branch to the hip-joint. Behind the Pectineus, it distributes branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare cases to the Pectineus; it receives a filament from the ~~accessory~~ obturator nerve when that nerve is present.

Occasionally the communicating branch to the anterior cutaneous and saphenous branches of the femoral nerve is continued down, as a cutaneous branch, to the thigh and leg. When this is so, it emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the medial side of the knee, where it pierces the deep fascia, communicates with the saphenous nerve, and is distributed to the skin half-way down the medial side of the leg.

The *posterior branch* pierces the anterior part of the Obturator externus, and supplies this muscle; it then passes behind the Adductor brevis on the front of the Adductor magnus, and divides into branches which are distributed to the Adductor magnus and to the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. It frequently gives off a slender *articular branch* to the knee-joint; this branch perforates the lower part of the Adductor magnus or passes through the opening which transmits the femoral artery, and enters the popliteal fossa; it here descends upon the popliteal artery, to the back of the knee-joint, where it pierces the oblique popliteal ligament, and is distributed to the articular capsule. It gives filaments to the popliteal artery.

FIG. 848.—The nerves of the right lower extremity. Front view.

The **accessory obturator nerve** (fig. 845) is present in about 20 per cent. of cases. It is of small size, and arises from the ventral divisions of the third and fourth lumbar nerves. It descends along the medial border of the Psoas major, crosses the superior ramus of the os pubis behind the Pectineus, and divides into branches. One branch enters the deep surface of the Pectineus; another goes to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. Occasionally the accessory obturator nerve is very small, and supplies only the hip-joint; when the nerve is absent, the hip-joint receives two branches from the obturator nerve.

The **femoral nerve** (anterior crural nerve) (fig. 848), the largest branch of the lumbar plexus, arises from the dorsal divisions of the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas major, emerging from the muscle at the lower part of its lateral border, and passes down between it and the Iliacus, behind the iliac fascia; it then runs beneath the inguinal ligament, into the thigh, and splits into an anterior and a posterior division. Under the inguinal ligament, it is separated from the femoral artery by a portion of the Psoas major.

Within the abdomen the femoral nerve gives off small branches to the Iliacus, and a branch which is distributed upon the upper part of the femoral artery; the latter branch may arise in the thigh.

The anterior division of the femoral nerve gives off anterior cutaneous and muscular branches. The anterior cutaneous branches comprise the intermediate and medial cutaneous nerves (fig. 846).

The *intermediate cutaneous nerve* pierces the fascia lata about 8 cm. below the inguinal ligament, either as two branches, or as a single trunk which quickly divides into two branches; these branches descend vertically along the front of the thigh, and supply the skin as low as the knee. They end in the patellar plexus (p. 917). The lateral branch of the intermediate cutaneous communicates with the lumbo-inguinal branch of the genitofemoral nerve, and frequently pierces the Sartorius.

The *medial cutaneous nerve* lies at first on the lateral side of the femoral artery, but at the apex of the femoral triangle it crosses in front of the artery and divides into two branches, an anterior and a posterior. The *anterior branch* runs downwards on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches: one supplies the integument as low down as the medial side of the knee; the other crosses to the lateral side of the patella, communicating in its course with the infrapatellar branch of the saphenous nerve. The *posterior branch* descends along the medial border of the Sartorius to the knee, where it pierces the fascia lata, communicates with the saphenous nerve, and gives off several cutaneous branches. It then passes down to supply the skin of the medial side of the leg. Beneath the fascia lata, at the lower border of the Adductor longus, it joins to form a plexiform network (*subsartorial plexus*) with branches of the saphenous and obturator nerves. When the communicating branch from the obturator nerve is large and continued to the skin of the leg, the posterior branch of the medial cutaneous is small, and terminates in the plexus, occasionally giving off a few cutaneous filaments.

The medial cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the skin of the medial side of the thigh, in the neighbourhood of the great saphenous vein; one of these filaments emerges through the fossa ovalis, and a second becomes subcutaneous about the middle of the thigh.

Muscular branches.—The *nerve to the Pectineus* arises just below the inguinal ligament, passes behind the femoral sheath and enters the anterior surface of the muscle; it is often duplicated. The *nerve to the Sartorius* arises in common with the intermediate cutaneous nerve.

The posterior division of the femoral nerve gives off the saphenous nerve, and muscular and articular branches.

The **saphenous nerve** (long or internal saphenous nerve) (fig. 848) is the largest cutaneous branch of the femoral nerve. It descends on the lateral side of the femoral artery and enters the adductor canal (p. 655) where it lies at first in front, and then on the medial side, of the femoral artery. At the lower end of the canal it quits the artery, and emerges through the aponeurotic

covering of the canal, accompanied by the saphenous branch of the highest genicular artery. It now descends vertically along the medial side of the knee behind the Sartorius, pierces the fascia lata, between the tendons of the Sartorius and Gracilis, and becomes subcutaneous. The nerve then passes along the tibial side of the leg, accompanied by the great saphenous vein, descends behind the medial border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, and ends at the ankle; the other passes in front of the ankle, and is distributed to the skin on the medial side of the foot, as far as the ball of the great toe, communicating with the medial branch of the superficial peroneal nerve.

Branches.—About the middle of the thigh, the saphenous nerve gives off a branch which joins the subsartorial plexus.

At the medial side of the knee it gives off a large *infrapatellar branch* (fig. 846) which pierces the Sartorius and fascia lata, and is distributed to the skin in front of the patella. This nerve communicates above the knee with the anterior cutaneous branches of the femoral nerve; below the knee, with other branches of the saphenous nerve; and, on the lateral side of the joint, with branches of the lateral femoral cutaneous nerve, forming a plexiform network, the *plexus patellæ*. The infrapatellar branch is occasionally small, and ends by joining the anterior cutaneous branches of the femoral nerve, which supply its place in front of the knee.

The *muscular branches* of the posterior division of the femoral nerve supply the four parts of the Quadriceps femoris. The branch to the Rectus femoris enters the upper part of the deep surface of the muscle, and supplies a filament to the hip-joint. The branch to the Vastus lateralis, of large size, accompanies the descending branch of the lateral femoral circumflex artery to the lower part of the muscle and sends an articular filament to the knee-joint. The branch to the Vastus medialis descends on the lateral side of the femoral vessels in company with the saphenous nerve. It enters the muscle about its middle, and gives off a filament, which can usually be traced downwards on the surface of the muscle, to the knee-joint. The branches to the Vastus intermedius, two or three in number, enter the anterior surface of the muscle about the middle of the thigh; a filament from one of these descends through the muscle to the Articularis genus and the knee-joint.

ANTERIOR DIVISIONS OF SACRAL AND COCCYGEAL NERVES

The anterior divisions of the sacral and coccygeal nerves form the sacral and pudendal plexuses. The anterior divisions of the upper four sacral nerves enter the pelvis through the anterior sacral foramina, that of the fifth between the sacrum and coccyx, while that of the coccygeal nerve curves forwards below the rudimentary transverse process of the first piece of the coccyx. The first and second sacral nerves are large; the third, fourth, and fifth diminish progressively from above downwards; the coccygeal nerve is the smallest. Each of these six nerves receives a grey ramus communicans from the corresponding ganglion of the sympathetic trunk, while from the second, third, and fourth sacral nerves, white rami communicantes are given to the pelvic plexuses of the sympathetic.

SACRAL PLEXUS

The *sacral plexus* (fig. 849) is formed by the lumbosacral trunk, the anterior division of the first, and portions of the anterior divisions of the second and third sacral nerves.

The lumbosacral trunk comprises the whole of the anterior division of the fifth and a part of that of the fourth lumbar nerve; it appears at the medial margin of the Psoas major and descends over the pelvic brim and in front of the sacro-iliac joint, to join the first sacral nerve. The anterior division of the third sacral nerve divides into an upper and a lower branch, the former entering the sacral plexus and the latter the pudendal plexus.

The nerves forming the sacral plexus converge towards the lower part of the greater sciatic foramen, and unite to form a flattened band, from the anterior and posterior surfaces of which several branches arise. The band itself is continued as the sciatic nerve, which splits on the back of the thigh

FIG. 849.—A plan of the sacral and pudendal plexuses.

into the tibial and common peroneal nerves. Sometimes these two nerves arise separately from the plexus, and in all cases their independence can be shown by dissection.

Relations.—The sacral plexus lies on the posterior wall of the pelvic cavity between the Piriformis and the pelvic fascia (fig. 850); in front of it are the hypogastric vessels, the ureter and the sigmoid colon. The superior gluteal vessels run between the lumbosacral trunk and the anterior division of the

first sacral nerve, and the inferior gluteal vessels between the anterior divisions of the second and third sacral nerves.

All the nerves entering the plexus, with the exception of the anterior division of the third sacral, split into ventral and dorsal divisions, and the nerves arising from these are as follows :

	Ventral divisions.	Dorsal divisions.
Nerve to Quadratus femoris and Gemellus inferior	4, 5 L., 1 S.	
Nerve to Obturator internus and Gemellus superior	5 L., 1, 2 S.	
Nerve to Piriformis		(1) 2 S.
Superior gluteal		4, 5 L., 1 S.
Inferior gluteal		5 L., 1, 2 S.
Posterior femoral cutaneous	2, 3 S.	1, 2 S.
Sciatic	4, 5 L., 1, 2, 3 S.	
Common peroneal		4, 5 L., 1, 2 S.

FIG. 850.—A dissection of the side wall of the pelvis, showing the sacral and pudendal plexuses.

The nerve to the Quadratus femoris and Gemellus inferior arises from the ventral divisions of the fourth and fifth lumbar and first sacral nerves : it leaves the pelvis through the greater sciatic foramen, below the Piriformis, and, running down on the ischium in front of the sciatic nerve, the Gemelli and the tendon of the Obturator internus, enters the anterior surfaces of the muscles ; it gives an articular branch to the hip-joint.

The nerve to the **Obturator internus** and **Gemellus superior** arises from the ventral divisions of the fifth lumbar and first and second sacral nerves. It leaves the pelvis through the greater sciatic foramen below the Piriformis, and gives off the branch to the **Gemellus superior**, which enters the upper part of the posterior surface of the muscle. It then crosses the ischial spine on the lateral side of the internal pudendal vessels, re-enters the pelvis through the lesser sciatic foramen, and pierces the pelvic surface of the **Obturator internus**.

The nerve to the **Piriformis** arises from the dorsal division of the second sacral nerve, or the dorsal divisions of the first and second sacral nerves, and enters the anterior surface of the muscle.

The **superior gluteal nerve** arises from the dorsal divisions of the fourth and fifth lumbar and first sacral nerves: it leaves the pelvis through the greater sciatic foramen above the Piriformis, accompanied by the superior gluteal vessels, and divides into a superior and an inferior branch. The *superior* branch accompanies the upper branch of the deep division of the superior gluteal artery and ends in the **Glutæus minimus**. The *inferior* branch runs with the lower branch of the deep division of the superior gluteal artery across the **Glutæus minimus**; it gives twigs to the **Glutæus medius** and **Glutæus minimus**, and ends in the **Tensor fasciæ latæ**.

The **inferior gluteal nerve** arises from the dorsal divisions of the fifth lumbar and first and second sacral nerves: it leaves the pelvis through the greater sciatic foramen below the Piriformis, and divides into branches which enter the deep surface of the **Glutæus maximus**.

The **posterior femoral cutaneous nerve** (small sciatic nerve) arises from the dorsal divisions of the first and second, and ventral divisions of the second and third sacral nerves, and issues from the pelvis through the greater sciatic foramen below the Piriformis. It then descends beneath the **Glutæus maximus** with the inferior gluteal artery, and runs down the back of the thigh beneath the fascia lata, and over the long head of the **Biceps femoris** to the back of the knee: here it pierces the deep fascia and accompanies the small saphenous vein to about the middle of the back of the leg, its terminal twigs communicating with the sural nerve.

Its branches are all cutaneous, and are distributed to the gluteal region, the perinæum, and the back of the thigh and leg.

The *gluteal branches* (nn. clunium inferiores), three or four in number, turn upwards round the lower border of the **Glutæus maximus**, and supply the skin covering the lower and lateral part of that muscle.

The *perinæal branches* are distributed to the skin at the upper and medial side of the thigh. One long perinæal branch (inferior pudendal) curves forwards below and in front of the ischial tuberosity, pierces the fascia lata, and runs forwards beneath the superficial fascia of the perinæum to the skin of the scrotum in the male, and of the labium majus in the female. It communicates with the inferior hæmorrhoidal and posterior scrotal nerves.

The *branches to the back of the thigh and leg* consist of numerous filaments derived from both sides of the nerve, and distributed to the skin covering the back and medial side of the thigh, the popliteal fossa, and the upper part of the back of the leg (fig. 851).

The **sciatic nerve** (fig. 853) is the largest nerve in the body. At its commencement it measures 2 cm. in breadth, and is the continuation of the flattened band of the sacral plexus. It passes out of the pelvis through the greater sciatic foramen, below the Piriformis muscle, descends between the greater trochanter of the femur and the tuberosity of the ischium, and along the back of the thigh to about its lower third, where it divides into two large branches, the tibial and common peronæal nerves. This division may take place at any point between the sacral plexus and the lower third of the thigh. When it occurs at the plexus, the common peronæal nerve usually pierces the Piriformis.

In the upper part of its course the nerve rests upon the posterior surface of the ischium, the nerve to the **Quadratus femoris**, the **Obturator internus** and **Gemelli**, and the **Quadratus femoris**; it is accompanied on its medial side by the posterior femoral cutaneous nerve and the inferior gluteal artery, and is covered by the **Glutæus maximus**. Lower down, it lies upon the **Adductor magnus**, and is crossed obliquely by the long head of the **Biceps femoris**.

The nerve gives off articular and muscular branches.

The *articular branches* arise from the upper part of the nerve and supply

FIG. 851.—The cutaneous nerves of the right lower extremity. Posterior view.

FIG. 852.—A diagram of the segmental distribution of the cutaneous nerves of the right lower extremity. Posterior view.

the hip-joint, perforating the posterior part of its capsule; they are sometimes derived from the sacral plexus.

The *muscular branches* are distributed to the Biceps femoris, Semitendinosus, Semimembranosus, and Adductor magnus. The nerve to the short head of the Biceps femoris comes from the common peroneal part of the sciatic.

FIG. 853.—The nerves of the right lower extremity.* Posterior view.

while the other muscular branches arise from the tibial portion, as may be seen in those cases where there is a high division of the sciatic nerve.

The tibial nerve (internal popliteal nerve) (fig. 853), the larger of the two terminal branches of the sciatic, arises from the ventral branches of the fourth and fifth lumbar and first, second, and third sacral nerves. It descends along the back of the thigh and through the middle of the popliteal fossa, to the lower part of the Popliteus muscle, whence it passes with the popliteal artery beneath the arch of the Soleus. It then runs along the back of the leg with the posterior tibial vessels to the interval between the medial malleolus and the heel, where it divides beneath the laciniato ligament into the medial and lateral plantar nerves. In the thigh it is overlapped by the hamstring muscles above, and then becomes more superficial, and lies laterally to, and some distance from, the popliteal vessels; opposite the knee-joint, it is superficial to these vessels, and then crosses to the medial side of the popliteal artery. In the leg it is covered in the upper part of its course by the superficial muscles of the calf; lower down by the skin and the superficial and deep fasciæ. It is placed on the deep muscles, and lies at first to the medial side of the posterior tibial artery, but soon crosses that vessel and descends on its lateral side as far as the ankle. In the lower third of the leg it runs parallel with the medial margin of the tendo calcaneus.

The branches of this nerve are: articular, muscular, medial sural cutaneous, medial calcaneal, medial and lateral plantar.

Articular branches, usually three in number, supply the knee-joint; two of these accompany the superior and inferior medial genicular arteries; and a third, the middle genicular artery. Just above its point of bifurcation the nerve gives an articular branch to the ankle-joint.

Muscular branches, four or five

* N.B.—In this diagram the medial sural cutaneous and peroneal anastomotic nerves have been displaced by the removal of the superficial muscles.

in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle; they supply that muscle, and the Plantaris, Soleus, and Popliteus. The branch for the Popliteus turns round the lower border of that muscle, and is distributed to its deep surface. Lower down, muscular branches arise separately or by a common trunk and supply the Soleus, Tibialis posterior, Flexor digitorum longus, and Flexor hallucis longus; the branch to the last muscle accompanies the peronæal artery; that to the Soleus enters the deep surface of the muscle.

The *medial sural cutaneous nerve* (n. communicans tibialis) descends between the two heads of the Gastrocnemius on to the superficial surface of the muscle, and, about the middle of the back of the leg, pierces the deep fascia, and unites with the peronæal anastomotic branch of the common peronæal nerve to form the sural nerve (fig. 851). The *sural nerve* (external saphenous nerve) passes downwards near the lateral margin of the tendo calcaneus, lying close to the small saphenous vein, to the interval between the lateral malleolus and the calcaneus; it supplies the skin of the lateral and posterior part of the lower third of the leg. It then runs forwards below the lateral malleolus, and is continued as the *lateral dorsal cutaneous nerve* along the lateral side of the foot and little toe, communicating on the dorsum of the foot with the intermediate dorsal cutaneous nerve, a branch of the superficial peronæal nerve. In the leg, its branches communicate with those of the posterior femoral cutaneous nerve.

The *medial calcaneal branch* perforates the lacinate ligament, and supplies the skin of the heel and medial side of the sole of the foot.

The *medial plantar nerve* (fig. 854), the larger of the two terminal divisions of the tibial nerve, accompanies the medial plantar artery. From its origin under the lacinate ligament it passes under cover of the Abductor hallucis, and, appearing between this muscle and the Flexor digitorum brevis, gives off a proper digital plantar nerve to the medial side of the great toe and finally divides opposite the bases of the metatarsal bones into three common digital plantar nerves.

Branches.—*Cutaneous branches* pierce the plantar aponeurosis between the Abductor hallucis and the Flexor digitorum brevis and are distributed to the skin of the sole of the foot.

Muscular branches supply the Abductor hallucis, the Flexor digitorum brevis, the Flexor hallucis brevis, and the first Lumbricalis; those for the Abductor hallucis and Flexor digitorum brevis arise from the trunk of the nerve near its origin and enter the deep surfaces of the muscles; the branch for the Flexor hallucis brevis springs from the proper digital nerve to the medial side of the great toe, and that for the first Lumbricalis from the first common digital nerve.

Articular branches supply the articulations of the tarsus and metatarsus.

The *proper digital nerve of the great toe* supplies the Flexor hallucis brevis and the skin on the medial side of the great toe.

The *three common digital nerves* pass between the divisions of the plantar aponeurosis, and each splits into two proper digital nerves. Those of the first common digital nerve supply the adjacent sides of the great and second toes; those of the second, the adjacent sides of the second and third toes; and those of the third, the adjacent sides of the third and fourth toes. The third common digital nerve receives a communicating branch from the lateral plantar nerve; the first gives a twig to the first Lumbricalis. Each proper digital nerve gives off cutaneous and articular filaments, and opposite the last phalanx sends upwards a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. It will be observed that the digital nerves of the medial plantar nerve are similar in their distribution to those of the median nerve in the hand.

The *lateral plantar nerve* (fig. 854) supplies the skin of the fifth toe and lateral half of the fourth, as well as most of the deep muscles, its distribution being similar to that of the ulnar nerve in the hand. It passes obliquely forwards with the lateral plantar artery to the lateral side of the foot, lying between the Flexor digitorum brevis and Quadratus plantæ, and, in the interval between the former muscle and the Abductor digiti quinti, divides into a superficial and a deep branch. Before its division, it supplies the Quadratus plantæ and Abductor digiti quinti.

The *superficial branch* splits into a proper and a common digital nerve; the proper digital nerve supplies the lateral side of the little toe, the Flexor digiti quinti brevis, and the two Interossei of the fourth intermetatarsal space; the common digital nerve communicates with the third common digital branch of the medial plantar nerve and divides into two proper digital nerves which supply the adjoining sides of the fourth and fifth toes.

The *deep branch* accompanies the lateral plantar artery on the deep surface of the tendons of the flexor muscles and the Adductor hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the second, third, and fourth Lumbricales, and the Adductor hallucis.

FIG. 854.—The plantar nerves.

FIG. 855.—A diagram of the segmental distribution of the cutaneous nerves of the sole of the foot.

✓ The common peroneal nerve (external popliteal nerve) (fig. 853), about one-half the size of the tibial, is derived from the dorsal branches of the fourth and fifth lumbar and the first and second sacral nerves. It descends obliquely along the lateral side of the popliteal fossa to the head of the fibula, close to the medial margin of the Biceps femoris muscle. It lies between the tendon of the Biceps femoris and lateral head of the Gastrocnemius muscle, winds round the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the superficial and deep peroneal nerves. Previous to its division it gives off articular and lateral sural cutaneous nerves.

The *articular branches* are three in number; two of these accompany the superior and inferior lateral genicular arteries to the knee; the upper one occasionally arises from the trunk of the sciatic nerve. The third, named the recurrent articular nerve, is given off at the point of division of the common peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anterior to the front of the knee.

The *lateral sural cutaneous nerve* supplies the skin on the posterior and lateral surfaces of the leg; one branch, the *peroneal anastomotic* (n. communicans fibularis), arises near the head of the fibula, crosses the lateral head

of the Gastrocnemius to the middle of the leg, and joins with the medial sural cutaneous to form the sural nerve (p. 923). The peronæal anastomotic nerve occasionally descends as a separate branch as far as the heel.

The deep peronæal nerve (anterior tibial nerve) (fig. 848) begins at the bifurcation of the common peronæal nerve, between the fibula and upper part of the Peronæus longus, passes obliquely forwards beneath the Extensor digitorum longus to the front of the interosseous membrane, and comes into relation with the anterior tibial artery in the upper third of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into a lateral and a medial terminal branch. It lies at first on the lateral side of the anterior tibial artery, then in front of it, and again on its lateral side at the ankle-joint.

In the leg, the deep peronæal nerve supplies *muscular branches* to the Tibialis anterior, Extensor hallucis longus, Extensor digitorum longus and Peronæus tertius, and an *articular branch* to the ankle-joint.

The *lateral terminal branch* passes across the tarsus, beneath the Extensor digitorum brevis, and, having become enlarged like the dorsal interosseous nerve at the wrist, supplies the Extensor digitorum brevis. From the enlargement three minute *interosseous branches* are given off, which supply the tarsal joints, and the metatarsophalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second Interosseus dorsalis muscle.

The *medial terminal branch* accompanies the dorsalis pedis artery along the dorsum of the foot, and, at the first interosseous space, communicates with the medial dorsal cutaneous branch of the superficial peronæal nerve, and divides into two dorsal digital nerves, which supply the adjacent sides of the great and second toes. Before it divides it gives off an *interosseous branch* which supplies the metatarsophalangeal joint of the great toe and sends a filament to the first Interosseus dorsalis muscle.

The superficial peronæal nerve (musculocutaneous nerve) (fig. 848) begins at the bifurcation of the common peronæal nerve, passes forwards between the Peronæi and the Extensor digitorum longus, pierces the deep fascia at the lower third of the leg, and divides into a medial and an intermediate dorsal cutaneous nerve. In its course between the muscles, it gives off muscular branches to the Peronæus longus and Peronæus brevis, and filaments to the skin of the lower part of the leg.

The *medial dorsal cutaneous nerve* passes in front of the ankle-joint, and divides into two dorsal digital branches, one of which supplies the medial side of the great toe, the other, the adjacent sides of the second and third toes. It also supplies the skin of the medial side of the foot and ankle, and communicates with the saphenous nerve and with the deep peronæal nerve (fig. 846).

The *intermediate dorsal cutaneous nerve*, the smaller, passes along the lateral part of the dorsum of the foot, and divides into dorsal digital branches, which supply the contiguous sides of the third and fourth, and of the fourth and fifth toes. It also supplies the skin of the lateral side of the foot and ankle, and communicates with the lateral dorsal cutaneous nerve (fig. 846).

The branches of the superficial peronæal nerve supply the skin of the dorsal surfaces of all the toes excepting the lateral side of the little toe and the adjoining sides of the great and second toes, the former being supplied by the lateral dorsal cutaneous branch of the sural nerve, and the latter by the medial branch of the deep peronæal nerve. Frequently some of the lateral branches of the superficial peronæal are absent, and their places are then taken by branches of the lateral dorsal cutaneous nerve.

PUDENDAL PLEXUS

The pudendal plexus (fig. 849) is not sharply marked off from the sacral plexus, and as a consequence some of the branches which spring from it arise in conjunction with those of the sacral plexus. It lies on the posterior wall of the pelvic cavity, and is usually formed by branches from the anterior divisions of the second, third, and fourth sacral nerves, the whole of the anterior divisions of the fifth sacral nerve and the coccygeal nerve.

It gives off the following branches :

Perforating cutaneous	2, 3 S.
Pudendal	2, 3, 4 S. <i>h</i>
Visceral	3, 4 S.
Muscular	4 S.
Anococcygeal	4, 5 S. and Cocc.

The **perforating cutaneous nerve** usually arises from the posterior surfaces of the second and third sacral nerves. It pierces the lower part of the sacrotuberous ligament, and, winding round the inferior border of the Glutæus maximus, supplies the skin covering the medial and lower parts of that muscle.

The perforating cutaneous nerve may arise from the pudendal or it may be absent : in the latter case its place may be taken by a branch from the posterior femoral cutaneous nerve or by a branch from the third and fourth, or fourth and fifth, sacral nerves.

The **pudendal nerve** (pudic nerve) derives its fibres from the ventral branches of the second, third, and fourth sacral nerves. It passes between the Piriformis and Coccygeus muscles and leaves the pelvis through the lower part of the greater sciatic foramen. It then crosses the spine of the ischium on the medial side of the internal pudendal vessels, and passes through the lesser sciatic foramen. It accompanies the internal pudendal vessels upwards and forwards along the lateral wall of the ischiorectal fossa, being contained with them in a sheath of the obturator fascia termed *Alcock's canal* ; after giving off the inferior hæmorrhoidal nerve, it divides into the perineal nerve, and the dorsal nerve of the penis or clitoris.

The *inferior hæmorrhoidal nerve* occasionally arises directly from the sacral plexus ; it crosses the ischiorectal fossa with the inferior hæmorrhoidal vessels, towards the anal canal and the lower end of the rectum, and is distributed to the Sphincter ani externus and to the skin round the anus. Branches of this nerve communicate with the perineal branch of the posterior femoral cutaneous and with the posterior scrotal nerves.

The *perineal nerve*, the inferior and larger terminal branch of the pudendal nerve, is situated below the internal pudendal artery. It accompanies the perineal artery and divides into posterior scrotal (or labial) and muscular branches.

The *posterior scrotal branches* (superficial perineal nerves) are two, a medial and a lateral. They pierce, or pass superficial to, the fascia of the urogenital diaphragm, and run forwards along the lateral part of the urethral triangle in company with the posterior scrotal branches of the perineal artery ; they are distributed to the skin of the scrotum, and communicate with the perineal branch of the posterior femoral cutaneous nerve. In the female the corresponding nerves (*posterior labial branches*) supply the *labium majus*.

The muscular branches are distributed to the *Transversus perinæi superficialis*, *Bulbocavernosus*, *Ischiocavernosus*, *Transversus perinæi profundus*, and *Sphincter urethræ membranaceæ*. A branch, the *nerve to the urethral bulb*, is given off from the nerve to the *Bulbocavernosus* ; it pierces this muscle, and supplies the *corpus cavernosum urethræ*, ending in the mucous membrane of the urethra.

The *dorsal nerve of the penis* is the deepest division of the pudendal nerve ; it accompanies the internal pudendal artery along the ramus of the ischium ; it then runs forwards along the margin of the inferior ramus of the os pubis, between the superior and inferior layers of the fascia of the urogenital diaphragm. Piercing the inferior layer it gives a branch to the *corpus cavernosum penis*, and passes forwards, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, and ends on the *glans penis*. In the female the corresponding nerve (*dorsal nerve of the clitoris*) is very small, and supplies the clitoris.

The *visceral branches* arise from the third and fourth, and sometimes from the second, sacral nerves, and are distributed to the bladder and rectum and, in the female, to the vagina ; they communicate with the pelvic plexuses of the sympathetic.

The *muscular branches* are derived from the fourth sacral, and supply the *Levator ani*, *Coccygeus*, and *Sphincter ani externus*. The branches to the

Levator ani and *Coccygeus* enter their pelvic surfaces; that to the *Sphincter ani externus* (perineal branch of fourth sacral nerve) reaches the ischio-rectal fossa by piercing the *Coccygeus* or by passing between it and the *Levator ani*. Cutaneous filaments from this branch supply the skin between the anus and the coccyx.

Anococcygeal nerves.—The anterior division of the fifth sacral nerve receives a communicating filament from the fourth, and unites with the minute anterior division of the coccygeal nerve to form the *coccygeal plexus*. From this plexus the anococcygeal nerves take origin; they consist of a few fine filaments which pierce the sacrotuberous ligament and supply the skin in the region of the coccyx.

Applied Anatomy.—The lumbar plexus passes through the *Psoas major*, and therefore in *psoas abscess* any or all of its branches may be irritated, causing severe pain in the part to which the irritated nerves are distributed. The genitofemoral nerve is the one which is most frequently implicated. This nerve is also of importance as it is concerned in one of the principal superficial reflexes employed in the investigation of diseases of the medulla spinalis. If the skin over the medial side of the thigh just below the inguinal ligament (the part supplied by the lumbo-inguinal branch of the genitofemoral nerve) be tickled in the male child, the testis will be retracted, through the action of the *Cremaster* muscle which is supplied by the external spermatic branch of the genitofemoral nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex shows that the portion of the medulla spinalis from which the first and second lumbar nerves are derived is in a normal condition.

The femoral nerve is in danger of being injured in fractures of the lesser pelvis, since the fracture most commonly takes place through the superior ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be pressed upon and its functions impaired, by some tumours growing in the pelvis. Moreover, on account of its superficial position, it is exposed to injury in wounds and stabs in the groin. Its central origin is often affected in cases of infantile paralysis. When this nerve is paralysed, the patient is unable to flex his hip completely, on account of the paralysis of the *Iliacus*; or to extend the knee on the thigh, on account of paralysis of the *Quadriceps femoris*; there is complete paralysis of the *Sartorius*, and partial paralysis of the *Pectineus*. There is loss of sensation down the front and medial side of the thigh, except in that part supplied by the lumbo-inguinal and ilio-inguinal nerves. There is also loss of sensation down the medial side of the leg and foot as far as the ball of the great toe.

The obturator nerve is rarely paralysed alone, but occasionally in association with the femoral. The principal interest attached to it is in connexion with its supply to the knee, pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient may not always complain of pain in that articulation, but on the medial side of the knee, or in the knee-joint itself, both of these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing may occur in sacro-iliac disease; or in cases of pathological growth of the ovary or tubal inflammation; or in cancer of the sigmoid colon; and even in cases where masses of hardened faeces are impacted in this portion of the gut, pain is complained of in the knee. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. When the obturator nerve is paralysed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the *Adductor* muscles. Rotation outwards of the thigh is impaired from paralysis of the *Obturator externus*. Sometimes there is loss of sensation in the upper half of the medial side of the leg.

The sciatic nerve is liable to be pressed upon by various forms of pelvic tumour, giving rise to pain along its trunk, to which the term *sciatica* is applied. Tumours growing from the pelvic viscera, especially advanced cancer of the rectum, aneurysms of some of the branches of the hypogastric artery, calculus in the bladder when of large size, accumulation of faeces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis, exostoses or other tumours growing from the margin of the greater sciatic foramen may also give rise to the same condition. Most cases of sciatica, however, are due to neuritis of the sciatic nerve from exposure to cold, and it occurs more often in men, in the latter half of life, and often in association with rheumatism, gout, or diabetes mellitus. The inflamed nerve is often sensitive to pressure, particularly in certain 'tender spots' (e.g. near the posterior iliac spine, at the sciatic notch, about the middle of the back of the thigh, in the popliteal fossa, below the head of the fibula, behind the malleoli, or on the dorsum of the foot), and pain is felt whenever extension of the leg is attempted and the nerve is stretched. Paralysis of the sciatic nerve is rarely complete; when the lesion occurs high up there is palsy of the *Biceps femoris*, *Semimembranosus*, and *Semitendinosus*, and of all the muscles below the knee. If the lesion be lower down, there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, which is supplied by the posterior femoral cutaneous, and in the upper half of the medial

side of the leg, when the communicating branch of the obturator is large (p. 915). Lesions of the common peroneal nerve cause paralysis of the *Tibialis anterior*, the *Peronæi*, the long Extensors of the toes, and the short Extensor on the dorsum of the foot. 'Foot-drop' follows, dorsal flexion of the toes and abduction of the foot being impossible. Later on, talipes of the equinovarus type results, due to the contracture of the unopposed posterior crural group of muscles.

The sciatic nerve has been frequently cut down upon and stretched, or has been acupunctured, for the relief of sciatica. In order to define it on the surface, a point is taken at the junction of the middle and lower thirds of a line stretching from the posterior superior spine of the ilium to the lateral part of the ischial tuberosity, and a line drawn from this to the middle of the upper part of the popliteal fossa. The line must be slightly curved with its convexity outwards, and, as it passes downwards to the lower border of the *Glutæus maximus*, is slightly nearer to the ischial tuberosity than to the greater trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve beneath the fold of the buttock. The skin, superficial structures, and deep fascia having been divided, the hamstrings are defined, and pulled apart with retractors. The nerve will be found lying on the Adductor magnus and covered by the Biceps femoris. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the 'dry' plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position, the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg.

The position of the common peroneal nerve, close behind the tendon of the Biceps femoris, on the lateral side of the popliteal fossa, should be remembered in subcutaneous division of the tendon. After the tendon is divided, the common peroneal nerve rises up as a cord, and might be mistaken for a small undivided portion of the tendon. Where this nerve winds round the neck of the fibula, it is also liable to be severed accidentally if its exact situation is not kept in mind, and especial care must be used when dealing with sinuses leading down to carious bone in this situation. Section of the nerve results in complete 'foot-drop' from paralysis of the anterior tibial group of muscles and inversion of the foot from the unopposed action of the *Tibialis posterior*, the *Peronæi* being paralysed, together with anesthesia of the parts supplied by the nerve, and, owing to loss of nutrition, the limb frequently becomes blue and cold, and may develop 'trophic' sores.

THE SYMPATHETIC NERVOUS SYSTEM

The sympathetic nerves are distributed to the viscera, glands and blood-vessels, and to unstriated muscle in general. They are characterised by the presence of numerous ganglia which may be divided into central, collateral and terminal groups.

The *central* ganglia are arranged in two vertical rows, one on either side of the middle line, and situated partly in front and partly at the sides of the vertebral column. The ganglia of each row are joined by intervening nervous cords, so that two trunks, named the *sympathetic trunks*, are formed. The *collateral* ganglia are found in connexion with three great *prevertebral plexuses* placed within the thorax, abdomen and pelvis and named respectively the *cardiac*, *celiac* and *hypogastric* plexuses. The *terminal* ganglia are located in the walls of the viscera.*

The efferent fibres of the sympathetic nerves originate as *preganglionic* fibres (p. 740) which are the axons of cells in the lateral grey column of the medulla spinalis. These fibres, medullated and mostly of small size, leave the medulla spinalis through the anterior nerve-roots of the spinal nerves in a thoracolumbar and a sacral group.

The *thoracolumbar* group of preganglionic fibres issue through the thoracic and the first and second lumbar nerves, and, leaving those nerves in the *white rami communicantes*, join the sympathetic trunks. Some of them end by forming synapses around the cells of the central ganglia of the sympathetic trunks. Others, after ascending or descending through the sympathetic trunks for varying distances, leave them and terminate in synapses around

*The ciliary, sphenopalatine, otic, and submaxillary ganglia, already described with the trigeminal nerve, form part of the autonomic system, and are closely allied to the sympathetic (p. 741).

the cells of the collateral ganglia in the prevertebral plexuses, or around the cells of the terminal ganglia in the walls of the viscera. All the preganglionic

FIG. 856.—The right sympathetic trunk and its connexions with the thoracic, abdominal, and pelvic plexuses. (After Schwalbe.)

fibres end by forming synapses around cells in the central, collateral or terminal sympathetic ganglia.

From the cells of the sympathetic ganglia fibres, mostly non-medullated, arise. Some of these fibres go directly, or through the prevertebral plexuses, to their distribution in the viscera, while others leave the sympathetic trunks in the *grey rami communicantes* and join the spinal nerves, through which they are conveyed to the blood-vessels, sudoriferous glands and Arrectores pilorum muscles.

The *sacral* group of preganglionic fibres emerge in the second, third and fourth sacral nerves and constitute the *pelvic splanchnic nerves* of Gaskell. They do not join the sympathetic trunks, but pass directly into the pelvic plexuses of the sympathetic; from the cells of these plexuses postganglionic fibres take origin and are distributed to the viscera of the pelvis.

FIG. 857.—A scheme showing the structure of a typical spinal nerve.

1. Somatic efferent. 2. Somatic afferent. 3, 4. Sympathetic efferent. 6, 7. Sympathetic afferent.

As already stated (p. 741) certain fine medullated fibres, homologous with the preganglionic fibres from the medulla spinalis, issue from the oculomotor, facial, glossopharyngeal, vagus and accessory cerebral nerves, and pass to peripherally placed ganglia. These fibres, together with those of the sympathetic system, constitute the *autonomic system*.

The afferent fibres of the sympathetic nerves originate in the cells of the spinal ganglia. The peripheral processes of these cells run in the white rami communicantes, and, after passing through one or more sympathetic ganglia (but always without interruption in them) end in the viscera, etc. The central processes enter the medulla spinalis through the posterior nerve-roots and form synapses around either somatic or sympathetic neurons.

The sympathetic trunks extend from the base of the skull to the coccyx. The superior extremity of each trunk is continued upwards under the name of the internal carotid nerve, through the carotid canal into the skull. Here it forms the carotid and cavernous plexuses which constitute the *cephalic part* of the sympathetic system. The inferior extremities of the sympathetic trunks converge and unite in a single ganglion, the *ganglion impar*, which is

placed in front of the coccyx. The ganglia of each trunk are distinguished as cervical, thoracic, lumbar, and sacral, and, except in the neck, their number corresponds more or less closely to that of the vertebræ. They are arranged thus :

Cervical portion	.	.	.	3 ganglia
Thoracic	„	.	.	12 „
Lumbar	„	.	.	4 „
Sacral	„	.	.	4 or 5 „

In the neck the ganglia lie in front of the transverse processes of the vertebræ; in the thoracic region in front of the heads of the ribs; in the lumbar region on the sides of the vertebral bodies; and in the sacral region in front of the sacrum.

CEPHALIC PORTION OF THE SYMPATHETIC SYSTEM

The cephalic portion of the sympathetic system on each side begins as the *internal carotid nerve*, which is continued upwards from the superior cervical ganglion of the sympathetic trunk. This nerve is soft in texture, and of a reddish colour. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, one of which lies on the lateral and the other on the medial side of the artery.

The *lateral branch*, the larger of the two, gives filaments to the internal carotid artery, and forms the *internal carotid plexus*.

The *medial branch* also supplies filaments to the internal carotid artery, and, continuing onwards, forms the *cavernous plexus*.

The *internal carotid plexus* is situated on the lateral side of the internal carotid artery, and in the plexus there occasionally exists a small gangliform swelling, the *carotid ganglion*, on the under surface of the artery. The plexus communicates with the semilunar and sphenopalatine ganglia, and with the abducent nerve and the tympanic branch of the glossopharyngeal nerve; it distributes filaments to the wall of the carotid artery.

The branches communicating with the abducent nerve consist of one or two filaments which join that nerve as it lies upon the lateral side of the internal carotid artery. The communication with the sphenopalatine ganglion is effected by a branch named the *deep petrosal*; this branch passes through the cartilage filling the foramen lacerum, and joins the greater superficial petrosal nerve to form the nerve of the pterygoid canal (Vidian nerve), which passes through the pterygoid canal to the sphenopalatine ganglion. The communication with the tympanic branch of the glossopharyngeal nerve is effected by the *superior and inferior carotidotympanic nerves* which traverse the wall of the carotid canal.

The *cavernous plexus*, formed chiefly by the medial division of the internal carotid nerve, is situated below and on the medial side of that part of the internal carotid artery which is placed by the side of the sella turcica, in the cavernous sinus. It gives branches to the internal carotid artery, and communicates with the oculomotor, trochlear, ophthalmic, and abducent nerves, and with the ciliary ganglion.

The branch to the oculomotor nerve joins that nerve at its point of division; the branch to the trochlear nerve joins the latter as it lies in the lateral wall of the cavernous sinus; filaments are connected with the medial side of the ophthalmic nerve; and one joins the abducent nerve. The filament to the ciliary ganglion arises from the anterior part of the cavernous plexus and enters the orbit through the superior orbital fissure; it may join the ganglion directly, or may unite with the long root of the ganglion.

The terminal filaments from the internal carotid and cavernous plexuses are prolonged as plexuses around the anterior and middle cerebral arteries and the ophthalmic artery: along the anterior and middle cerebral arteries they may be traced to the pia mater; along the ophthalmic artery into the orbit where they accompany each of the branches of that vessel. The filaments prolonged on to the anterior communicating artery connect the sympathetic nerves of the right and left sides.

CERVICAL PORTION OF THE SYMPATHETIC SYSTEM

The cervical portion of each sympathetic trunk consists of three ganglia, distinguished, according to their positions, as the superior, middle, and inferior, connected by intervening cords. This portion receives no white rami communicantes from the cervical spinal nerves; its spinal fibres are derived from the white rami of the upper thoracic nerves, and enter the corresponding thoracic ganglia of the sympathetic trunk, through which they ascend into the neck.

The superior cervical ganglion, the largest of the three, is placed opposite the second and third cervical vertebrae. It is of a reddish-grey colour, and usually fusiform in shape, sometimes broad and flattened, and occasionally constricted at intervals; it is believed to be formed by the coalescence of four ganglia, corresponding to the upper four cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, with the Longus capitis muscle. The internal carotid nerve (p. 931) ascends from the upper end of the ganglion into the cranial cavity; the lower end of the ganglion is united by the connecting trunk with the middle cervical ganglion.

Its branches may be divided into lateral, medial, and anterior.

The lateral branches consist of grey rami communicantes to the upper four cervical nerves and to certain of the cerebral nerves. Sometimes the branch to the fourth cervical nerve may come from the trunk connecting the upper and middle cervical ganglia. Delicate filaments run to the ganglion nodosum of the vagus, and to the hypoglossal nerve, and a branch, named the *jugular nerve*, ascends to the base of the skull, and divides into two twigs, one of which joins the petrous ganglion of the glossopharyngeal, and the other the jugular ganglion of the vagus.

The medial branches are the laryngopharyngeal branches and the superior cardiac nerve.

The *laryngopharyngeal branches* pass to the side of the pharynx, where they join with branches from the glossopharyngeal and vagus nerves to form the *pharyngeal plexus*. From this plexus branches pass to the muscles and mucous membrane of the pharynx, and communicate with the superior laryngeal nerve.

The *superior cardiac nerve* arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the trunk between the superior and middle cervical ganglia. It runs down the neck behind the common carotid artery, and in front of the Longus colli muscle; and crosses in front of the inferior thyroid artery, and recurrent nerve. The course of the nerve of the right side then differs from that of the left. The *right nerve*, at the root of the neck, passes either in front of or behind the subclavian artery, and along the innominate artery to the back of the arch of the aorta, where it joins the deep part of the cardiac plexus. It is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two twigs (upper cervical branches) from the vagus; and as it enters the thorax it is joined by a filament from the recurrent nerve. Filaments from the nerve communicate with the thyroid branches from the middle cervical ganglion. The *left nerve*, in the thorax, runs in front of the left common carotid artery and across the left side of the arch of the aorta, to the superficial part of the cardiac plexus. Sometimes it descends on the right side of the aorta and ends in the deep part of the cardiac plexus.

The anterior branches ramify upon the common carotid artery and upon the external carotid artery and its branches, forming round each a delicate plexus in which small ganglia are occasionally found. The plexus surrounding the external maxillary artery supplies a filament to the submaxillary ganglion, and the plexus on the middle meningeal artery sends one offset to the otic ganglion, and another, the *external petrosal nerve*, to the genicular ganglion of the facial nerve.

The middle cervical ganglion is the smallest of the three cervical ganglia, and is occasionally wanting. It is placed opposite the sixth cervical vertebra, usually in front of, or close to, the inferior thyroid artery. It is probably

formed by the coalescence of two ganglia corresponding with the fifth and sixth cervical nerves.

It sends grey rami communicantes to the fifth and sixth cervical nerves, and gives off thyreoid branches, and the middle cardiac nerve.

The *thyreoid branches* run along the inferior thyreoid artery to the thyreoid gland; they communicate with the superior cardiac, external laryngeal and recurrent nerves.

The *middle cardiac nerve*, the largest of the three cardiac nerves, arises from the middle cervical ganglion, or from the trunk between the middle and inferior ganglia. On the *right side* it descends behind the common carotid artery, and at the root of the neck runs either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent nerve, and joins the right half of the deep part of the cardiac plexus. In the neck, it communicates with the superior cardiac and recurrent nerves. On the *left side*, the middle cardiac nerve enters the thorax between the left carotid and subclavian arteries, and joins the left half of the deep part of the cardiac plexus.

The *inferior cervical ganglion* is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib, on the medial side of the costocervical trunk. Its form is irregular; it is larger in size than the preceding, and is frequently fused with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the seventh and eighth cervical nerves. It is connected to the middle cervical ganglion by two or more cords, one of which forms a loop around the subclavian artery, and supplies offsets to it. This loop is named the *ansa subclavia* (*Vieussensii*).

The ganglion sends grey rami communicantes to the seventh and eighth cervical nerves, gives off the inferior cardiac nerve, and supplies branches to blood-vessels.

The *inferior cardiac nerve* arises from either the inferior cervical or the first thoracic ganglion. It descends behind the subclavian artery and along the front of the trachea, to join the deep part of the cardiac plexus. Behind the subclavian artery it communicates with the recurrent and middle cardiac nerves.

The *offsets to blood-vessels* form plexuses on the subclavian artery and its branches. The plexus on the vertebral artery is continued on to the basilar, posterior cerebral, and cerebellar arteries. The plexus on the inferior thyreoid artery accompanies the artery to the thyreoid gland, and communicates with the recurrent and external laryngeal nerves, with the superior cardiac nerve, and with the plexus on the common carotid artery.

THORACIC PORTION OF THE SYMPATHETIC SYSTEM (fig. 858)

The thoracic portion of the sympathetic trunk consists on either side of a series of ganglia, which usually correspond in number to that of the vertebræ; but, on account of the occasional coalescence of two ganglia, their number is variable. The thoracic ganglia, with the exception of the last two, rest against the heads of the ribs, and are covered by the costal pleura; the last two are placed on the sides of the bodies of the eleventh and twelfth thoracic vertebræ. The ganglia are small, and of a greyish colour. The first is larger than the others, and of an elongated form; it is frequently blended with the inferior cervical ganglion. The ganglia are connected together by the intervening portions of the trunk.

Two rami communicantes, a white and a grey, connect each ganglion with its corresponding spinal nerve.

The *branches from the upper five ganglia* are very small; they supply filaments to the thoracic aorta and its branches. On the aorta they form, together with filaments from the great splanchnic nerve, a delicate plexus (*plexus aorticus thoracalis*). Twigs from the second, third, and fourth ganglia enter the posterior pulmonary plexus.

The *branches from the lower seven ganglia* are large, and white in colour; they distribute filaments to the aorta, and unite to form the greater, the lesser, and the lowest splanchnic nerves.

The *greater splanchnic nerve* is of a considerable size, and consists mainly of medullated fibres; it is formed by branches from the fifth to the ninth or tenth thoracic ganglia, but the fibres in the higher roots may be traced upwards in the sympathetic trunk as far as the first or second thoracic ganglion. It descends obliquely on the bodies of the vertebræ, perforates the crus of the Diaphragm, and ends in the celiac ganglion. A ganglion (*ganglion splanchnicum*) exists on this nerve opposite the eleventh or twelfth thoracic vertebra.

FIG. 858.—The thoracic portion of the left sympathetic trunk.

The *lesser splanchnic nerve* is formed by filaments from the ninth and tenth, sometimes the tenth and eleventh, thoracic ganglia, and from the trunk between the ganglia. It pierces the Diaphragm with the preceding nerve, and joins the aorticorenal ganglion.

The *lowest splanchnic nerve* arises from the last thoracic ganglion. It pierces the Diaphragm with the sympathetic trunk, and ends in the renal plexus.

A striking analogy exists between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they arise from the cervical ganglia,

and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, arise from the thoracic ganglia, and are distributed to organs in the abdominal cavity.

ABDOMINAL PORTION OF THE SYMPATHETIC SYSTEM (fig. 859)

The abdominal portion of each sympathetic trunk is situated in front of the vertebral column, along the medial margin of the Psoas major. It consists usually of four lumbar ganglia, connected together by interganglionic cords. It is continuous above with the thoracic portion, beneath the medial lumbocostal arch; below with the pelvic portion, behind the common iliac artery.

Grey rami communicantes pass from all the ganglia to the lumbar spinal nerves. The first and second, and sometimes the third, lumbar nerves send white rami communicantes to the corresponding ganglia. The rami communicantes are of considerable length, and accompany the lumbar arteries around the sides of the bodies of the vertebrae, passing beneath the fibrous arches which give origin to some of the fibres of the Psoas major.

Of the *branches of distribution*, some pass in front of the aorta, and join the abdominal aortic plexus; others descend in front of the common iliac arteries, and assist in forming the hypogastric plexus.

PELVIC PORTION OF THE SYMPATHETIC SYSTEM (fig. 856)

The pelvic portion of each sympathetic trunk is situated in front of the sacrum, medially to the anterior sacral foramina. It consists of four or five small sacral ganglia, connected together by interganglionic cords, and continuous above with the abdominal portion. Below, the two pelvic sympathetic trunks converge, and unite on the front of the coccyx in a small ganglion, the *ganglion impar* or *coccygeal ganglion*.

Grey rami communicantes pass from the ganglia to the sacral and coccygeal nerves. No white rami communicantes are given to this part of the gangliated cord, but the visceral branches which arise from the second, third and fourth sacral nerves, and run directly to the pelvic plexuses, are regarded as white rami communicantes.

The *branches of distribution* communicate on the front of the sacrum with the corresponding branches from the opposite side; twigs from the first two ganglia join the pelvic plexus, and others form a plexus on the middle sacral artery. Filaments are distributed to the glomus coccygeum (coccygeal body) from the loop uniting the two trunks.

The following facts concerning the course of the sympathetic nerve-fibres have been arrived at by experiments on lower animals, chiefly dogs, but they probably hold good for the human sympathetic system:—

The sympathetic fibres for the head and neck leave the medulla spinalis through the upper five thoracic nerves (chiefly through the second and third nerves). They ascend in the cervical part of the sympathetic trunk and end in the superior cervical ganglion. The fibres arising from the cells of this ganglion are vasoconstrictor for the blood-vessels, secretory for the salivary and sudoriferous glands, and dilator for the pupil.

The accelerator fibres of the heart leave mainly through the second and third thoracic nerves and pass to the *stellate ganglion*. From the cells of this ganglion fibres are distributed to the heart.

Fibres leave the thoracic spinal nerves (mainly the lower six) and are conveyed through the splanchnic nerves to the celiac ganglion, from the cells of which fibres pass to the blood-vessels and viscera of the abdominal cavity. Fibres from the lower thoracic and upper three or four lumbar nerves pass through the ganglia of the lumbar part of the sympathetic trunk to the inferior mesenteric ganglion; from this ganglion fibres are conveyed through the hypogastric and pelvic plexuses to the pelvic viscera.

No spinal fibres pass from the sacral nerves to the sympathetic trunks, but the visceral branches of the second, third and fourth sacral nerves correspond to white rami communicantes and enter the pelvic sympathetic plexuses. From these plexuses fibres are conveyed to the pelvic viscera, and vasodilator fibres (*nervi erigentes*) to the penis.

The constrictor fibres for the blood-vessels of the upper limbs leave the thoracic nerves from about the fourth to the tenth inclusive; those for the lower limbs through the lower two or three thoracic and upper three lumbar nerves.

* In the dog the upper four thoracic ganglia of the sympathetic trunk are fused into one mass which is named the *stellate ganglion*.

FIG. 859.—The abdominal portion of the sympathetic trunks, with the coeliac and hypogastric plexuses. (After Henle.)

THE GREAT PLEXUSES OF THE SYMPATHETIC

The great plexuses of the sympathetic are aggregations of nerves and ganglia, situated in the thoracic, abdominal, and pelvic cavities, and named the cardiac, coeliac, and hypogastric plexuses. They consist not only of sympathetic fibres derived from the ganglia, but of fibres from the medulla spinalis, which are conveyed through the white rami communicantes. From the plexuses branches are given to the thoracic, abdominal, and pelvic viscera.

CARDIAC PLEXUS (fig. 856)

The cardiac plexus is situated at the base of the heart, and is divided into a *superficial* and a *deep part*, which are, however, closely connected.

The *superficial part* of the cardiac plexus lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the superior cardiac branch of the left sympathetic trunk and the lower of the superior cardiac branches of the left vagus. A small ganglion, the *cardiac ganglion of Wisberg*, is occasionally found connected with these nerves at their point of junction; when present it is situated immediately beneath the arch of the aorta, on the right side of the ligamentum arteriosum. The superficial part of the cardiac plexus gives branches (a) to the deep part of the plexus; (b) to the anterior coronary plexus; and (c) to the left anterior pulmonary plexus.

The *deep part* of the cardiac plexus is situated in front of the bifurcation of the trachea, above the point of division of the pulmonary artery, and behind the aortic arch. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic trunk, and the cardiac branches of the vagus and recurrent nerves. The only cardiac nerves which do not join the deep part of the cardiac plexus are the superior cardiac nerve of the left sympathetic trunk, and the lower of the superior cardiac branches from the left vagus nerve, which pass to the superficial part of the plexus.

The branches from the *right half* of the deep part of the cardiac plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onwards to form part of the anterior coronary plexus; those behind the pulmonary artery distribute a few filaments to the right atrium, and are then continued onwards to form part of the posterior coronary plexus.

The *left half* of the deep part of the plexus is connected with the superficial part of the cardiac plexus, and gives filaments to the left atrium, and to the anterior pulmonary plexus, and is then continued to form the greater part of the posterior coronary plexus.

The *posterior coronary plexus* is larger than the anterior, and accompanies the left coronary artery; it is formed chiefly by filaments prolonged from the left half of the deep part of the cardiac plexus, and by a few from the right half. It gives branches to the left atrium and ventricle.

The *anterior coronary plexus* is formed partly from the superficial and partly from the deep parts of the cardiac plexus. It accompanies the right coronary artery, and gives branches to the right atrium and ventricle.

The upper cardiac nerves are distributed to the ascending aorta, the pulmonary artery and the ventricles; the lower cardiac nerves, to the atria.

COELIAC PLEXUS (figs. 856, 860)

The coeliac or solar plexus, the largest of the three great sympathetic plexuses, is situated at the level of the upper part of the first lumbar vertebra, and is composed of two large ganglia, the coeliac ganglia, and a dense network of nerve-fibres uniting them together. It surrounds the coeliac artery and the root of the superior mesenteric artery. It lies behind the stomach and the omental bursa, in front of the crura of the Diaphragm and the commencement of the abdominal aorta, and between the suprarenal glands. The plexus and the ganglia receive the greater and lesser splanchnic nerves of both sides

and some filaments from the right vagus, and give off numerous secondary plexuses along the neighbouring arteries.

The *cœliac* or *semilunar ganglia* are two large irregularly-shaped masses having the appearance of lymph-glands, and placed one on either side of the middle line in front of the crura of the Diaphragm close to the suprarenal glands, that on the right side being placed behind the inferior vena cava. The upper part of

FIG. 860.—The *cœliac* ganglia with the sympathetic plexuses of the abdominal viscera radiating from the ganglia. (From Toldt's 'Atlas,' published by Messrs. Rebman, Ltd., London.)

each ganglion is joined by the greater splanchnic nerve, while the lower part, which is more or less detached, and named the *aorticorenal* ganglion, receives the lesser splanchnic nerve and gives off the greater part of the renal plexus.

The secondary plexuses springing from or connected with the *cœliac* plexus are the following :

Phrenic.
Hepatic.
Lienal.
Superior gastric.
Suprarenal.

Renal.
Spermatic.
Superior mesenteric.
Abdominal aortic.
Inferior mesenteric.

The phrenic plexus accompanies the inferior phrenic artery to the Diaphragm, some filaments passing to the suprarenal gland. It arises from the upper part of the coeliac ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. At the point of junction of the right phrenic plexus with the phrenic nerve is a small ganglion (*ganglion phrenicum*). This plexus distributes some branches to the inferior vena cava, and to the suprarenal and hepatic plexuses.

The hepatic plexus, the largest offset from the coeliac plexus, receives filaments from the left vagus and right phrenic nerves. It accompanies the hepatic artery, ramifying upon its branches, and upon those of the portal vein, in the substance of the liver. Branches from this plexus accompany all the branches of the hepatic artery. A considerable plexus accompanies the gastroduodenal artery and is continued as the *inferior gastric plexus* on the right gastro-epiploic artery along the greater curvature of the stomach, where it unites with offshoots from the lienal plexus.

The lienal or splenic plexus is formed by branches from the coeliac plexus, left coeliac ganglion, and right vagus nerve. It accompanies the lienal artery to the spleen, giving off, in its course, subsidiary plexuses along the various branches of the artery.

The superior gastric plexus accompanies the left gastric artery along the lesser curvature of the stomach, and joins with branches from the left vagus.

The suprarenal plexus is formed by branches from the coeliac plexus, from the coeliac ganglion, and from the phrenic and greater splanchnic nerves, a ganglion being formed at the point of junction with the latter nerve. The plexus supplies the suprarenal gland, and is distributed chiefly to its medullary portion; its branches are remarkable for their large size in comparison with that of the organ they supply.

The renal plexus is formed by filaments from the coeliac plexus, the aorticorenal ganglion, and the aortic plexus. It is joined also by the smallest splanchnic nerve. The nerves from these sources, fifteen or twenty in number, have a few ganglia developed upon them. They accompany the branches of the renal artery into the kidney; some filaments are distributed to the spermatic plexus and to the ureter, and, on the right side, to the inferior vena cava.

The spermatic plexus is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the testicular artery to the testis. In the female, the ovarian plexus arises from the renal plexus, and is distributed to the ovary, and the fundus of the uterus.

Applied Anatomy.—The intimate connexion which exists between the renal and spermatic plexuses serves to explain the very frequent symptom, in renal calculus, of pain which is referred to the body of the testis.

The superior mesenteric plexus is a continuation of the lower part of the coeliac plexus, and receives a branch from the junction of the right vagus nerve with the plexus. It surrounds the superior mesenteric artery, accompanies it into the mesentery, and divides into a number of secondary plexuses which are distributed to all the parts supplied by the artery, viz. pancreatic branches to the pancreas; jejunal and ileal branches to the small intestine; and ileocolic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves composing this plexus are white in colour and firm in texture; in the upper part of the plexus close to the origin of the superior mesenteric artery is a ganglion (*ganglion mesentericum superius*).

The abdominal aortic plexus is formed by branches derived, on either side, from the coeliac plexus and ganglia, and receives filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; it also distributes filaments to the inferior vena cava.

The inferior mesenteric plexus is derived chiefly from the aortic plexus. It surrounds the inferior mesenteric artery, and just below the origin of this vessel the *inferior mesenteric ganglion* is situated. The plexus divides into a number of secondary plexuses, which are distributed to all the parts supplied.

by the artery; thus the left colic and sigmoid plexuses supply the descending and sigmoid parts of the colon; and the superior hæmorrhoidal plexus, supplies the rectum and joins in the pelvis with branches from the pelvic plexuses.

HYPOGASTRIC PLEXUS (fig. 856)

The **hypogastric plexus** is situated in front of the last lumbar vertebra and the promontory of the sacrum, between the two common iliac arteries. It is formed by the union of numerous filaments, which descend on either side from the aortic plexus, and from the lumbar ganglia. It divides, below, into two lateral portions which are named the *pelvic plexuses*.

PELVIC PLEXUSES (fig. 856)

The **pelvic plexuses** supply the viscera of the pelvic cavity, and are situated at the sides of the rectum in the male, and at the sides of the rectum and vagina in the female. They are formed on either side by a continuation of the hypogastric plexus, by the visceral branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two ganglia of the sacral part of the sympathetic trunk. At the points of junction of these nerves small ganglia are found. From these plexuses numerous branches are distributed to the viscera of the pelvis. They accompany the branches of the hypogastric artery.

The **middle hæmorrhoidal plexus** arises from the upper part of the pelvic plexus; it supplies the rectum, and joins with branches of the superior hæmorrhoidal plexus.

The **vesical plexus** arises from the fore part of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed to the sides and fundus of the bladder. Numerous filaments also pass to the vesiculæ seminales and ductus deferentes; those accompanying the ductus deferentes join, on the spermatic cords, with branches from the spermatic plexuses.

The **prostatic plexus** is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate, vesiculæ seminales, and the corpora cavernosa of the penis and urethra. The nerves supplying the corpora cavernosa consist of two sets, the lesser and greater cavernous nerves, which arise from the fore part of the prostatic plexus, and, after joining with branches from the pudendal nerve, pass forwards beneath the pubic arch.

The *lesser cavernous nerves* perforate the fibrous covering of the penis, near its root, and are distributed to its erectile tissue.

The *greater cavernous nerve* passes forwards along the dorsum of the penis, joins with the dorsal nerve of the penis, and is distributed to the corpora cavernosa.

The **vaginal plexus** arises from the lower part of the pelvic plexus. It is distributed to the walls of the vagina and to the erectile tissue of the vestibule. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve-fibres.

The **uterine plexus** accompanies the uterine artery along the side of the uterus, between the layers of the broad ligament, and communicates with the ovarian plexus. Its fibres are chiefly distributed to the neck, and the lower part of the body, of the uterus. At the side of the neck of the uterus is a collection of small ganglia which together form the *uterine cervical ganglion*.

Applied Anatomy.—Little is known as to the connexion between the numerous microscopical alterations (pigmentation, atrophy, hæmorrhage, fibrosis) that have been described in the sympathetic nervous system, and the functional changes that ensue therefrom. Grosser lesions due to stabs, bullet-wounds, or the pressure of new growths, may cause either irritative or paralytic symptoms. In *paralysis* of the cervical sympathetic on one side, the pupil is small and does not dilate when shaded or on the instillation of cocaine, although it contracts still further when brightly illuminated; it also loses the oculo-spinal reflex, failing to dilate when the skin of the neck is pinched. The palpebral fissure narrows from paralysis of the involuntary muscle of the eyelid, and the

eyeball sinks backwards into the orbit—enophthalmos—either from paralysis of Müller's orbital muscle in the eyelids, which surrounds the eyeball like a conical cuff and tends to produce exophthalmos when it contracts, or from wasting of the intraorbital fat. The superficial vessels of the face and scalp are at first dilated, but later they contract. Anidrosis, or absence of sweating, is often noted on the affected side. Irritation of the cervical sympathetic produces signs mainly the converse of those described above. We have no definite knowledge of the signs and symptoms that follow lesions of the thoracic or abdominal sympathetic systems. It is likely, however, that a number of nervous disorders characterised by persistent vascular disturbances, such as dilatation of the vessels with throbbing, flushing, sweating, and localised oedema, or contraction of the vessels with pallor, chilliness, pain, and malnutrition of the affected parts, are due to implication of the sympathetic nervous system. It is possible, too, that the rare condition of *progressive facial hemiatrophy*, coming on between the ages of ten and twenty, and producing marked unilateral shrinkage of all the tissues on the affected side of the face, is primarily an affection of the sympathetic.

THE ORGANS OF THE SENSES AND THE COMMON INTEGUMENT

THE organs of the senses may be divided into (a) those of the special senses of taste, smell, sight, and hearing, and (b) those associated with the general sensations of heat, cold, pain, pressure, &c.

PERIPHERAL ORGANS OF THE SPECIAL SENSES

THE ORGAN OF TASTE

The peripheral gustatory organs, or organs of taste, consist of certain modified epithelial cells arranged in flask-shaped groups termed *gustatory calyculi* or

FIG. 861.—A vertical transverse section of the papilla foliata of the rabbit. (Ranvier.)

a. Serous gland. g. Gustatory calyculus. n. Nerve-bundles. p. Central lamina of the corium. p'. Lateral lamina in which the nerve-fibres run. v. Sinus-like vein which traverses the whole length of the folium.

taste-buds, which are found on the tongue and adjacent parts. They occupy nests in the stratified epithelium (fig. 861), and are very numerous on the sides of the papillæ vallatæ and less so on the walls surrounding the papillæ. They are also found on the fungiform papillæ over the posterior part and sides of the tongue, and in the general epithelial covering of the same areas. They are very plentiful over the fimbriæ linguæ, and are also present on the under surface of the soft palate, and on the posterior surface of the epiglottis.

Structure.—Each taste-bud is flask-shaped (fig. 862), its broad base resting on the corium, and its neck opening by an orifice, the *gustatory pore*, between the cells of the epithelium. The bud consists of supporting cells and gustatory cells. The *supporting cells* are mostly arranged like the staves

of a cask, and form a complete envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The *gustatory cells* occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near the middle of the cell. The peripheral process of the cell ends at the gustatory pore in a fine hair-like filament, the *gustatory hair*. The central process passes towards the deep extremity of the bud, and there ends in a single or branched extremity. The nerve-fibres, after losing their medullary sheaths, enter the taste-bud, and end in fine fibrils between the gustatory cells; other nerve-fibrils end between the epithelial cells which surround the taste-bud, but these are believed to be nerves of ordinary sensation and not gustatory.

FIG. 862.—A taste-bud, highly magnified.

Nerves of taste.—The chorda tympani nerve, derived from the sensory root of the facial nerve, and distributed with the lingual nerve, is the nerve of taste for the anterior two-thirds of the tongue; the glossopharyngeal is the nerve of taste for the posterior one-third of the tongue.

THE ORGAN OF SMELL

The peripheral olfactory organ or organ of smell consists of two parts: an outer, the *external nose*, which projects from the centre of the face; and an internal, the *nasal cavity*, which is divided by a septum into *right* and *left nasal chambers*.

The *external nose* is pyramidal in form, and its upper angle or *root* is connected directly with the forehead; its free angle is termed the *apex*. Its *base* is perforated by two elliptical orifices, the *nares*, separated from each other by an antero-posterior septum, the *columna*. The lateral surfaces of the nose form, by their union in the middle line, the *dorsum nasi*, the direction of which varies considerably in different individuals; the upper part of the dorsum is supported by the nasal bones, and is named the *bridge*. The lateral surfaces end below in rounded eminences, the *ala nasi*.

FIG. 863.—The cartilages of the nose. Side view.

The framework of the external nose is composed of bones and cartilages. The *bony framework* occupies the upper part of the organ; it consists of the nasal bones, the frontal processes of the maxillæ, and the nasal part of the frontal bone. The *cartilaginous framework* consists of five large pieces, viz. the cartilage of the septum, the two lateral, and the two greater alar, cartilages, and several smaller pieces, the lesser alar cartilages (figs. 863, 864, 865). The various cartilages are connected to each other and to the bones by a tough fibrous membrane.

The *cartilage of the septum* is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal cavities in front. Its anterior margin, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the lateral cartilages; below, it is connected to the medial crura of the greater alar cartilages by fibrous tissue. Its posterior margin is connected with the lamina perpendicularis of the

ethmoidal bone; its lower margin with the vomer and the incisor crest of the maxillæ. It may extend backwards (especially in children) as a narrow process, the *sphenoidal process*, for some distance between the vomer and the lamina perpendicularis of the ethmoidal bone. In front, the septal cartilage does not

FIG. 864.—The cartilages of the nose.
From below.

form the lower part of the nasal septum. This is formed by the medial crura of the greater alar cartilages and by the skin; it is freely movable, and hence is termed the *septum mobile nasi*.

The *lateral cartilage* is situated below the inferior margin of the nasal bone, and is flattened, and triangular in shape. Its anterior margin is thicker than the posterior, and is continuous above with the cartilage of the septum, but separated from it below by a narrow fissure; its superior margin is attached to the nasal bone and the frontal process of the maxilla; its inferior margin is connected by fibrous tissue with the greater alar cartilage.

The *greater alar cartilage* is a thin, flexible plate, situated immediately below the lateral cartilage, and bent upon itself in such a manner as to form the medial, anterior, and lateral walls of the naris of its own side. The portion which forms the medial wall (*crus mediale*) is narrow, and is loosely connected with the corresponding portion of the opposite cartilage, the two forming, together with the thickened skin and subjacent tissue, the *septum mobile nasi*. The part which forms the lateral wall (*crus laterale*) is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the frontal process of the maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the *lesser alar cartilages*. Above, it is connected by fibrous tissue to the lateral cartilage and front part of the cartilage of the septum; below, it falls short of the lateral margin of the naris, the ala being completed by fatty and fibrous tissue covered by skin. In front, the greater alar cartilages are separated by a notch which corresponds with the apex of the nose.

FIG. 865.—The bones and cartilages of the septum of the nose. Right side.

The *muscles* acting on the external nose have been described on p. 429.

The *skin* of the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts; but over the tip and ala it is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The *arteries* of the external nose are the alar and septal branches of the external maxillary artery, which supply the alæ and septum; the dorsum and sides being supplied from the dorsal nasal branch of the ophthalmic artery and the infraorbital branch of the internal maxillary artery. The *veins* end in the anterior facial and ophthalmic veins.

The *nerves* for the muscles of the nose are derived from the facial nerve, while the skin receives branches from the infratrochlear and anterior ethmoidal branches of the ophthalmic nerve, and from the infraorbital branch of the maxillary nerve.

Nasal cavities.—The nasal cavities or chambers are situated one on either side of the median plane. They open in front through the nares, and communicate behind with the nasal part of the pharynx through the choanae. The *nares* are somewhat pear-shaped apertures, each measuring from 1.5 cm.

to 2 cm. anteroposteriorly, and from 0.5 cm. to 1 cm. transversely at its widest part. The *choanae* are two oval openings each measuring 2.5 cm. in the vertical, and 1.25 cm. in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal cavities, see p. 256.

Inside the aperture of the nostril is a slight dilatation, the *vestibule*, bounded laterally by the ala and the lateral crus of the greater alar cartilage, and medially by the medial crus of the same cartilage; it extends as a small recess towards the apex of the nose. The vestibule is lined by skin, and in its lower part are coarse hairs and sebaceous glands; the hairs (*vibrissae*) curve downwards and forwards and arrest the passage of foreign substances carried with the current of inspired air. The vestibule is limited above and behind by a curved elevation, the *limen nasi*, along which the cutaneous lining of the vestibule is continuous with the mucous membrane of the nasal cavity.

FIG. 866.—The lateral wall of the right nasal cavity.

Each nasal cavity, above and behind the vestibule, is divided into two parts: an *olfactory* region, limited to the superior nasal concha and the opposed part of the septum, and a *respiratory* region, which comprises the rest of the cavity.

Lateral wall (figs. 866, 867).—On the lateral wall are the superior, middle, and inferior nasal conchæ, and below and lateral to each concha is the corresponding nasal passage or meatus. Above the superior concha is a triangular fossa, the *spheno-ethmoidal recess*, into which the sphenoidal sinus opens. The *superior meatus* is a short oblique passage extending about half-way along the upper border of the middle concha; the posterior ethmoidal cells open, usually by two apertures, into the front part of this meatus. The *middle meatus*, deeper in front than behind, is below and lateral to the middle concha, and is continued anteriorly into a shallow depression, situated above the vestibule and named the *atrium* of the middle meatus. Above the atrium a flattened ridge, termed the *agger nasi*, and better developed in the new-born child than in the adult, runs forwards and downwards; the furrow above

it is named the *sulcus olfactorius*. On raising or removing the middle concha the lateral wall of this meatus is fully displayed. On it is a round elevation, the *bullæ ethmoidalis*, and below and in front of this is a curved cleft, the *hiatus semilunaris*. The *bullæ ethmoidalis* is caused by the bulging of the middle ethmoidal cells which open on or immediately above it, and the size of the bulla varies with that of its contained cells. The *hiatus semilunaris* is bounded inferiorly by the sharp concave margin of the uncinæ process of the ethmoidal bone, and leads into a curved channel, the *infundibulum*, bounded above by the bulla ethmoidalis and below by the lateral surface of the uncinæ process of the ethmoidal bone. The anterior ethmoidal cells open into the front part of the infundibulum; the latter in rather more than 50 per cent.

FIG. 867.—The lateral wall of the right nasal cavity; the three nasal conchæ have been removed.

of subjects is continuous with the frontonasal duct or passage leading from the frontal air-sinus; but in those cases where the anterior end of the uncinæ process fuses with the front part of the bulla, this continuity is interrupted and the frontonasal duct then opens directly into the anterior end of the middle meatus. Below the bulla ethmoidalis, and partly hidden by the inferior end of the uncinæ process, is the *ostium maxillare*, or opening from the maxillary sinus; in a frontal section of the nose this opening is seen to be placed near the roof of the sinus. An accessory opening from the sinus is frequently present below and behind the infundibulum. The *inferior meatus* is below and lateral to the inferior nasal concha; the nasolacrimal duct opens into this meatus under cover of the anterior part of the inferior concha.

Medial wall (fig. 865).—The medial wall or septum is frequently more or less deflected from the median plane, thus lessening the size of one nasal cavity and increasing that of the other; ridges or spurs of bone growing into one or other cavity from the septum are also sometimes present. Immediately over the incisive canal at the lower edge of the cartilage of the septum a depression, the *nasopalatine recess*, is sometimes seen; it points downwards and forwards,

and occupies the position of a canal which connected the nasal with the buccal cavity in early foetal life. In the septum close to this recess a minute orifice may be discerned; it leads backwards into a blind pouch, the rudimentary *vomeranasal organ of Jacobson*, which is supported by a strip of cartilage, the *vomeranasal cartilage*. This organ is well developed in many of the lower animals, where it apparently plays a part in the sense of smell, since it is supplied by twigs of the olfactory nerve and is lined by epithelium similar to that in the olfactory region of the nose.

The *roof* of the nasal cavity is narrow from side to side, except at its posterior part, and may be divided, from behind forwards, into sphenoidal, ethmoidal, and frontonasal parts, corresponding to the bones which form it.

The *floor* is concave from side to side, flat and almost horizontal antero-posteriorly; its anterior three-fourths are formed by the palatine process of the maxilla, its posterior fourth by the horizontal part of the palatine bone.

The *nasal mucous membrane* lines the nasal cavities with the exception of the vestibules, and is intimately adherent to the periosteum or perichondrium.

FIG. 868.—A section of the olfactory mucous membrane. (Cadiat.)

a. Epithelium. b. Glands of Bowman. c. Nerve-bundles.

It is continuous with the mucous membrane of the nasal part of the pharynx, through the choanæ; with the conjunctiva, through the nasolacrimal and lacrimal ducts; and with the mucous membranes of the frontal, ethmoidal, sphenoidal, and maxillary sinuses, through the openings of these sinuses into the sphenoidal recess and the superior and middle meatuses.

The mucous membrane is thickest and most vascular over the nasal conchæ, especially at their extremities. It is also thick over the septum nasi; but it is very thin in the meatuses, on the floor of the nasal cavities, and in the various air-sinuses. Owing to the thickness of the membrane, the nasal cavities are much narrower, and the middle and inferior nasal conchæ appear larger and more prominent than in the skeleton; the various apertures communicating with the meatuses are also considerably narrowed.

Structure of the mucous membrane (fig. 868).—The epithelium of the mucous membrane differs in its characteristics according to the functions of the part of the nose in which it is found. In the *respiratory region* it is columnar and ciliated. Interspersed among the columnar cells are goblet or mucous cells, while between their bases are found smaller pyramidal cells. Beneath the epithelium and its basement membrane is a fibrous layer infiltrated with lymph-corpuscles, forming in many parts a diffuse adenoid tissue, and under this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the *olfactory region* the mucous membrane is yellowish in colour and the epithelial cells are columnar and non-ciliated; they are of two kinds, supporting cells and olfactory cells.

The *supporting cells* contain oval nuclei, which are situated in the deeper parts of the cells and constitute the zone of oval nuclei; the superficial part of each cell is columnar, and contains granules of yellow pigment, while its deep part is prolonged as a delicate process which ramifies, and communicates with similar processes from neighbouring cells so as to form a network in the mucous membrane. Lying between the deep processes of the supporting cells are a number of bipolar nerve-cells, the *olfactory cells*, each consisting of a small amount of granular protoplasm with a large spherical nucleus, and possessing two processes—a superficial process which runs between the columnar epithelial cells, and ends at the surface of the mucous membrane in one or more fine, hair-like processes, the *olfactory hairs*; the deep process runs inwards, is frequently beaded, and is continued as an olfactory nerve-fibre (p. 847). Beneath the epithelium, and extending through the thickness of the mucous membrane, is a layer of tubular, often branched, glands, the *glands of Bowman*, similar in structure to serous glands.

Vessels and Nerves.—The *arteries* of the nasal cavities are the anterior and posterior ethmoidal branches of the ophthalmic artery, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the sphenopalatine branch of the internal maxillary artery, which supplies the mucous membrane covering the conchæ, the meatuses, and septum;

FIG. 869.—The nerves of the septum of the nose. Right side.

the septal ramus of the superior labial branch of the external maxillary artery; the infraorbital and alveolar branches of the internal maxillary artery, which supply the lining membrane of the maxillary sinus; and the pharyngeal branch of the same artery, distributed to the sphenoidal sinus. The ramifications of these vessels form a close plexiform network, beneath and in the substance of the mucous membrane.

The *veins* form a close cavernous plexus beneath the mucous membrane. This plexus is especially marked over the lower part of the septum and over the middle and inferior conchæ. Some of the veins open into the sphenopalatine vein; others join the anterior facial vein; some accompany the ethmoidal arteries, and end in the ophthalmic veins; a few communicate with the veins on the orbital surface of the

frontal lobe of the brain, through the foramina in the lamina cribrosa of the ethmoidal bone. When the foramen cecum is patent it transmits a vein from the nasal cavity to the superior sagittal sinus.

The *lymphatics* are described on p. 717.

The *nerves* of ordinary sensation are: the anterior ethmoidal branch of the nasociliary nerve, filaments from the anterior alveolar branch of the maxillary nerve, the nerve of the pterygoid canal, the nasopalatine, the anterior palatine and nasal branches of the sphenopalatine ganglion.

The anterior ethmoidal branch of the nasociliary nerve distributes filaments to the anterior parts of the septum and lateral wall. Filaments from the anterior alveolar nerve supply the inferior meatus and inferior concha. The nerve of the pterygoid canal supplies the upper and posterior parts of the septum, and superior concha; and the upper nasal branches from the sphenopalatine ganglion have a similar distribution. The nasopalatine nerve supplies the middle of the septum. The anterior palatine nerve supplies the lower nasal branches to the middle and inferior conchæ.

The *olfactory nerve* is distributed to the olfactory region. Its fibres arise from the bipolar olfactory cells and are destitute of medullary sheaths. They unite in fasciculi which cross one another in various directions, and thus give rise to the appearance of a plexus in the mucous membrane, and then ascend in grooves or canals in the ethmoidal bone; they pass into the skull through the foramina in the lamina cribrosa of the ethmoid and enter the under surface of the olfactory bulb, in which they ramify and form synapses with the dendrites of the mitral cells (fig. 806).

ACCESSORY SINUSES OF THE NOSE (figs. 866, 867, 870)

The **accessory sinuses** or **air-cells** of the nose are the frontal, ethmoidal, sphenoidal, and maxillary; they vary in size and form in different individuals, and are lined by mucous membrane continuous with that of the nasal cavities.

The **frontal sinuses**, two in number, are situated behind the superciliary arches; they are rarely symmetrical, and the septum between them frequently deviates to one or other side of the middle line. Their average measurements are as follows: height, 3.16 cm.; breadth, 2.58 cm.; depth from before backwards, 1.8 cm. Each opens into the anterior part of the corresponding middle meatus of the nose through the frontonasal duct, which traverses the anterior part of the labyrinth of the ethmoid. Small at birth, they are generally fairly well developed between the seventh and eighth years, but only reach their full size after puberty.

Fig. 870.—A coronal section of the nasal cavities.

The **ethmoidal air-cells** consist of numerous thin-walled cavities situated in the ethmoidal labyrinth, and completed by the frontal, maxillary, lacrimal, sphenoidal and palatine bones. They lie between the upper parts of the nasal cavities and the orbits, and are separated from the latter by thin bony laminae. On either side they are arranged in three groups, anterior, middle, and posterior. The anterior and middle groups open into the middle meatus of the nose, the former by way of the infundibulum, the latter on or above the bulla ethmoidalis. The posterior cells open into the superior meatus under cover of the superior nasal concha; sometimes one or more opens into the sphenoidal sinus. The ethmoidal cells begin to develop during foetal life.

The **sphenoidal sinuses**, two in number, are contained within the body of the sphenoidal bone; they vary in size and shape, and, owing to the lateral displacement of the intervening septum, are rarely symmetrical. The following are their average measurements: vertical height, 2 cm.; transverse breadth, 1.8 cm.; antero-posterior depth, 2.1 cm. When exceptionally large they may extend into the roots of the pterygoid processes or great wings, and may invade the basilar part of the occipital bone. Each sinus communicates with the spheno-ethmoidal recess by

an aperture in the upper part of its anterior wall. They are present as minute cavities at birth, but their main development takes place after puberty.

The **maxillary sinus** or **antrum of Highmore**, the largest of the accessory sinuses of the nose, is a pyramidal cavity in the body of the maxilla. Its base is formed by the lateral wall of the nasal cavity, and its apex extends into the zygomatic process. Its roof or orbital wall is frequently ridged by the infraorbital canal, while its floor is formed by the alveolar process and is usually about 1.25 cm. below the level of the floor of the nose; projecting into the floor are several conical elevations corresponding with the roots of the first and second molar teeth, and in some cases it is perforated by one or more of these roots. The size of the sinus varies in different skulls, and even on the two sides of the same skull; when large, its apex may invade the zygomatic bone. The following measurements are those of an average-sized sinus: vertical height opposite the first molar tooth, 3.5 cm.; transverse breadth, 2.5 cm.; anteroposterior depth, 3.2 cm. In the anterosuperior part of its base is an opening through which it communicates with the lower part of the hiatus semilunaris; a second orifice is frequently seen in, or immediately behind, the hiatus. The maxillary sinus appears as a shallow groove on the medial surface of the bone about the fourth month of fetal life, but does not reach its full size until after the second dentition.*

Applied Anatomy.—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the external nose, an aperture only being present, or perfect development on one side, and suppression or malformation on the other. Deformities which have been acquired are much more common, such as flattening of the nose, the result of syphilitic necrosis; or imperfect development of the nasal bones in cases of congenital syphilis; or a lateral deviation of the nose after fracture.

The septum of the nose may be displaced or may deviate from the middle line as a result of an injury or of some congenital defect. Sometimes the deviation may be so great that the septum may come into contact with the lateral wall of the nasal cavity, producing complete unilateral obstruction. The septum is covered by a mucous membrane intimately connected with the periosteum; in cases of deflection of the septum, *submucous resection* is frequently necessary, the septal cartilage and the vomer being shelled out from the mucoperiosteum clothing them. Perforation of the septum is not uncommon, and most often results from syphilitic ulceration.

Enlargement of the mucous membrane covering the inferior or middle nasal conchæ is a very frequent accompaniment of chronic nasal catarrh. In old-standing cases the bones themselves may become enlarged, constituting the 'hypertrophied turbinals' which so often cause nasal obstruction. In the case of the inferior concha either the anterior or posterior end is usually more especially affected, giving rise to a reddened mass of tissue often confused with a nasal polypus; the appearances, however, are totally different, as the true nasal polypi appear as glistening greyish-white bodies between the conchæ.

Nasal polypi are of frequent occurrence; in the common gelatinous form they spring from the lateral wall of the nasal cavity and project down between the conchæ, giving rise to obstructed nasal respiration. They are always accompanied by purulent discharge, and are due in all instances to small areas of carious bone in the region of the *bullæ ethmoidalis*, or about the ethmoidal or sphenoidal air-cells. In bad cases a free curetting of the ethmoidal air-cells may be called for after removal of the middle concha. Fibrous polypi are also more rarely met with, and these are of the nature of new growths; they most frequently spring from the base of the skull behind the choanæ and form pedunculated tumours occupying the nasopharynx. Malignant polypi also occur, most commonly originating in the maxillary sinus and projecting through its medial wall into the nasal cavity; for such cases removal of the maxilla offers the only hope of cure.

Suppuration in the accessory nasal sinuses is of frequent occurrence, and in connexion with this the situations at which the various sinuses normally communicate with the nasal cavities, are important: thus one finds they fall into two main groups: the anterior, opening into the middle meatus, and draining the maxillary sinus, the frontal sinus, and the anterior ethmoidal air-cells; and the posterior group, opening into the superior meatus and sphenoid-ethmoidal recess, and draining the posterior ethmoidal and sphenoidal air-cells. Suppuration in the anterior group is the more common, and the pus can be seen running down over the anterior end of the inferior concha, whereas in the case of the posterior group, the pus does not come forwards, but runs back into the nasopharynx over the posterior end of the middle concha. Again, it is of importance to notice that the middle meatus is of such a form that pus running down from the frontal sinus is directed by the groove beneath the *bullæ ethmoidalis* into the ostium of the maxillary sinus, so that the latter sinus may, in some cases, act as a secondary reservoir for pus discharged from the frontal sinus. All the accessory sinuses can be and are infected from the nasal cavity, but it should be noted that in the case of the maxillary sinus, the infection is frequently

* The various measurements of the accessory sinuses of the nose are those given by A. Logan Turner, *Accessory Sinuses of the Nose*, 1901.

conveyed in another way, and that is from the teeth. This sinus is the one most frequently the seat of chronic suppuration and it often requires drainage; this can be carried out by drilling a hole through the alveolus after removal of a tooth, preferably the first molar, or by gouging away the anterior surface of the maxilla, after having reflected the gum, or by removing bone from the lateral wall of the inferior meatus of the nose. Simple drainage, however, is not usually sufficient, and more extensive operations have often to be performed. Distension of the walls of the maxillary antrum occurs as the result of new growth or cyst formation within its cavity. Thus the facial surface may be prominently bulged outwards, upward extension may displace the eyeball, or the nasal cavity on that side may be occluded, giving rise to unilateral obstruction. In some cases the disease will perforate the palatine process of the maxilla and a soft spot will be found under the mucoperiosteum. If the disease be malignant in nature, nothing short of excision of the maxilla is of any avail (p. 265).

THE ORGAN OF SIGHT

The bulb of the eye (eyeball), or organ of sight, is contained in the cavity of the orbit, where it is protected from injury, and can be moved by the ocular muscles. Associated with it are certain accessory structures, viz. the muscles, fasciæ, eyebrows, eyelids, conjunctiva, and lacrimal apparatus.

The bulb of the eye, enveloped by a thin membranous sac, the *fascia bulbi* (p. 972), is imbedded in the fat of the orbit. It is composed of segments of two hollow spheres of different sizes. The anterior segment is one of a small sphere; it is transparent, and forms about one-sixth of the bulb. It is more prominent than the posterior segment, which is one of a larger sphere, and is opaque, and forms about five-sixths of the bulb. The term *anterior pole* is applied to the central point of the anterior curvature of the bulb, and that of *posterior pole* to the central point of its posterior curvature; a line joining the two poles forms the *optic axis*. The axes of the two bulbs are nearly parallel, and therefore do not correspond with the axes of the orbits, which are directed forwards and lateralwards. The optic nerves follow the direction of the axes of the orbits, and are therefore not parallel; each enters its eyeball 3 mm. to the nasal side of and a little below the level of the posterior pole. The bulb measures rather more in its transverse and anteroposterior diameters than in its vertical diameter, the former amounting to about 24 mm., the latter to about 23.5 mm.; its anteroposterior diameter at birth is about 17.5 mm. and at puberty from 20 to 21 mm. In the female all three diameters are rather less than in the male.

The bulb of the eye is composed of three tunics, enclosing three refracting media.

TUNICS OF THE EYE (fig. 871)

From without inwards the three tunics are: (1) A fibrous tunic, consisting of the *sclera* behind and the *cornea* in front; (2) a vascular pigmented tunic, comprising, from behind forwards, the *chorioid*, *ciliary body*, and *iris*; and (3) a nervous tunic, the *retina*.

I. FIBROUS TUNIC

The sclera and cornea (fig. 871) form the fibrous tunic of the bulb of the eye; the sclera is opaque, and constitutes the posterior five-sixths of the tunic; the cornea is transparent, and forms the anterior one-sixth.

The sclera has received its name from its extreme density and hardness; it is a firm unyielding membrane, serving to maintain the form of the bulb. It is thickest (about 1 mm.) behind, near the entrance of the optic nerve, and thinnest (0.4 mm.) at a distance of about 6 mm. behind the sclerocorneal junction. Its *external surface* is white, and is in contact with the inner surface of the fascia of the bulb; it is smooth, except where the Recti and Obliqui are inserted into it; its anterior part is covered by the conjunctival membrane. Its *inner surface* is brown and is marked by grooves, in which the ciliary nerves and vessels are lodged; it is separated from the outer surface of the chorioid by an extensive *perichorioid* lymph-space, which is traversed by an exceedingly

fine cellular tissue, the *lamina suprachorioidea*. Behind, it is pierced by the optic nerve, and is continuous through the fibrous sheath of this nerve with the dura mater. The optic nerve pierces the sclera through a cribriform lamina, the *lamina cribrosa scleræ*; the minute orifices in this lamina serve for the transmission of the nervous filaments, and the fibrous septa dividing them from one another are continuous with the supporting trabeculæ of the nerve. One opening, larger than the rest, occupies the centre of the lamina; it transmits the central artery and vein of the retina. Around the lamina cribrosa scleræ are numerous small apertures for the transmission of the ciliary vessels and nerves, and about midway between these and the sclerocorneal junction are four or five large apertures for the transmission of veins (*venæ vorticosæ*). In front, the sclera is directly continuous with the cornea, the line of union being termed the *sclerocorneal junction*. In the substance of the sclera close

FIG. 871.—A horizontal section of the bulb of the eye.

to this junction is a circular canal, the *sinus venosus scleræ* (canal of Schlemm). In a meridional section of the sclerocorneal junction this sinus presents the appearance of a cleft, the outer wall of which consists of the firm tissue of the sclera, while its inner wall is formed by a triangular mass of trabecular tissue (fig. 872); the apex of the mass is directed forwards and is continuous with the posterior elastic lamina of the cornea. The sinus is lined by endothelium and communicates internally with the anterior chamber of the eye and externally with the anterior ciliary veins.

Structure.—The sclera is formed of white fibrous tissue intermixed with fine elastic fibres; flattened connective tissue corpuscles, some of which are pigmented, are contained in cell-spaces between the fibres. The fibres are aggregated into bundles, which are arranged chiefly in a longitudinal direction. Its *vessels* are not numerous; its capillaries are small, and unite at long and wide intervals. Its *nerves* are derived from the ciliary nerves, but their exact mode of ending is not known.

The cornea is the projecting transparent part of the external tunic, and forms the anterior one-sixth of the surface of the bulb. It is almost circular in

outline, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects like a dome in front of the sclera. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, being more pronounced in youth than in advanced life. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in diameter. Immediately in front of the sclerocorneal junction the cornea bulges inwards as a thickened rim, and behind this there is a distinct furrow between the attachment of the iris and the sclerocorneal junction. This furrow has been named by Arthur Thomson * the *sulcus circularis corneæ*;

FIG. 872.—An enlarged general view of the iridial angle. (Arthur Thomson.)

it is bounded externally by the trabecular tissue already described as forming the inner wall of the sinus venosus scleræ. Between this tissue and the anterior surface of the attached margin of the iris is an angular recess, named the *iridial angle* or *filtration angle* of the eye (fig. 872). Immediately outside the filtration angle is a projecting rim of scleral tissue which appears in a meridional section as a small triangular area, termed the *scleral spur*. Its base is continuous with the inner surface of the sclera immediately to the outer side of the filtration angle and its apex is directed forwards and inwards. The bundles of trabecular tissue just referred to are attached to the anterior sloping margin of this spur; the meridional fibres of the Ciliaris muscle arise from its posterior margin.

Structure (fig. 873).—The cornea consists from before backwards of four layers, viz.: (1) the corneal epithelium, continuous with that of the conjunctiva; (2) the

* *Atlas of the Eye*, Clarendon Press, Oxford, 1912.

substantia propria; (3) the posterior elastic lamina; and (4) the endothelium of the anterior chamber.

The *corneal epithelium* covers the front of the cornea and consists of several layers of cells. The cells of the deepest layer are columnar; then follow two or three layers of polyhedral cells, the majority of which are prickle-cells similar to those found in the stratum mucosum of the cuticle.

FIG. 878.—A vertical section of the human cornea from near its margin. (Waldeyer.) Magnified.

1. Epithelium. 2. Anterior elastic lamina. 3. Substantia propria. 4. Posterior elastic lamina. 5. Endothelium of the anterior chamber. a. Oblique fibres in the anterior layer of the substantia propria. b. Lamellæ the fibres of which are cut across, producing a dotted appearance. c. Corneal corpuscles appearing fusiform in section. d. Lamellæ the fibres of which are cut longitudinally. e. Transition to the sclera, with more distinct fibrillation, and surmounted by a thicker epithelium. f. Small blood-vessels cut across near the margin of the cornea.

Lastly, there are three or four layers of squamous cells, with flattened nuclei.

The *substantia propria* is fibrous, tough, unyielding, and perfectly transparent. It is composed of about sixty flattened, superimposed lamellæ. These lamellæ are made up of bundles of modified connective tissue, the fibres of which are continuous with those of the sclera. The fibres of each lamina are for the most part parallel with one another, but at right angles to those of adjacent lamellæ. Fibres, however, frequently pass from one lamella to the next.

Between the lamellæ is a small amount of ground-substance, in which are spaces, the *corneal spaces*. These are stellate in shape and communicate with one another by numerous offsets. Each contains a cell, the *corneal corpuscle*, resembling in form the space in which it is lodged, but not entirely filling it.

The layer immediately beneath the corneal epithelium presents certain characteristics which have led some anatomists to regard it as a distinct membrane, and it has been named the *anterior elastic lamina*. It differs, however, from the posterior elastic lamina in showing evidence of fibrillar structure, and in not having the same tendency to curl inwards, or to undergo

fracture, when detached from the other layers of the cornea. It consists of extremely closely interwoven fibrils, similar to those found in the substantia propria, but contains no corneal corpuscles. It may be regarded as a condensed part of the substantia propria.

The *posterior elastic lamina* covers the posterior surface of the substantia propria, and is an elastic, transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by water, alcohol, or acids. When stripped from the substantia propria it curls up, or rolls upon itself, with the attached surface innermost.

At the margin of the cornea the posterior elastic lamina breaks up into fibres which form the trabecular tissue on the inner wall of the sinus venosus scleræ (p. 952); the spaces between the trabeculæ are termed the *spaces of the angle of the iris* (spaces of Fontana); they communicate with the sinus venosus scleræ and with the anterior chamber at the filtration angle. Some of the fibres of this trabecular tissue are continued into the substance of the iris, forming the *pectinate ligament of the iris*; while others are connected with the fore part of the sclera and choroid.

The *endothelium of the anterior chamber* covers the posterior surface of the posterior elastic lamina, is reflected on to the front of the iris, and also lines the spaces of the angle of the iris; it consists of a layer of polygonal, flattened, nucleated cells.

Vessels and Nerves.—The cornea is a non-vascular structure, the capillary vessels of the conjunctiva and sclera ending in loops at its circumference. Lymphatic vessels have not yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these channels are lined by an endothelium. The *nerves* are numerous and are derived from the ciliary nerves. Around the periphery of the cornea they form an *annular plexus*, from which fibres enter the substantia propria. They lose their medullary sheaths and ramify throughout the substantia propria in a delicate network, and their terminal filaments form a firm and closer plexus on the surface of the cornea proper, beneath the epithelium. This is termed the *subepithelial plexus*, and from it fibrils are given off which ramify between the epithelial cells, forming an *intra-epithelial plexus*.

II. THE VASCULAR TUNIC (figs. 874, 875, 876)

The vascular tunic of the eye is formed from behind forwards by the choroid, the ciliary body, and the iris.

The choroid covers the inner surface of the sclera, and extends as far forwards as the ora serrata of the retina. The ciliary body connects the choroid with the circumference of the iris. The iris is a circular diaphragm behind the cornea, and presents near its centre a rounded aperture, the *pupil*.

The choroid is a thin, highly vascular membrane, of a dark brown or chocolate colour, investing the posterior five-sixths of the globe; it is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclera. It is thicker behind than in front. Its outer surface is loosely connected with the sclera by the lamina supra-chorioidea; its inner surface is attached to the pigmented layer of the retina.

Structure.—The choroid consists mainly of a dense capillary plexus, and of small arteries and veins carrying blood to, and returning it from, this plexus. On its external surface is a thin membrane, the *lamina supra-chorioidea*, composed of delicate non-vascular lamellæ, each lamella consisting of a network of fine elastic fibres among which are branched pigment-cells. The spaces between the lamellæ are lined by endothelium, and open freely into the perichoroidal lymph-space, which, in its turn, communicates with the periscleral space at the points where the vessels and nerves are transmitted through the sclera.

FIG. 874.—The choroid and iris. (Enlarged.)

1. The *stratum opticum* or *layer of nerve-fibres* is formed by the expansion of the fibres of the optic nerve; it is thickest near the *porus opticus*, gradually diminishing towards the *ora serrata*. As the nerve-fibres pass through the *lamina cribrosa sclerae*, they lose their medullary sheaths and are continued onwards through the chorioid and retina as simple axis-cylinders. When they reach the internal surface of the retina they radiate from their point of entrance over this surface, grouped in bundles which communicate with one another and form an intricate network. Most of the types are centripetal, and are the continuations of the axis-cylinder processes of the cells of the ganglionic layer, but a few are centrifugal; these originate in the brain and ramify in the inner plexiform and inner nuclear layers of the retina, where they end in enlarged extremities.

2. The *ganglionic layer* consists of a single layer of large nerve-cells, except in the *macula lutea*, where there are several strata. The cells are somewhat flask-shaped, the rounded internal surface of each resting on the *stratum opticum*, and

FIG. 884.—A plan of the retinal neurons. (After Ramón y Cajal.)

sending off an axon which is prolonged into it. From the opposite end numerous dendrites extend into the inner plexiform layer, where they form flattened arborisations at different levels. The ganglion-cells vary much in size, and the dendrites of the smaller ones as a rule arborise in the inner plexiform layer as soon as they enter it; while those of the larger cells ramify close to the inner nuclear layer.

3. The *inner plexiform layer* is made up of a dense reticulum of minute fibrils formed by the interlacement of the dendrites of the ganglion-cells with the processes of the cells of the inner nuclear layer; within this reticulum a few branched cells are imbedded.

4. The *inner nuclear layer* is made up of a number of closely packed cells, of which there are three varieties, viz. bipolar cells, horizontal cells, and amacrine cells.

The *bipolar cells*, by far the most numerous, are round or oval in shape, and each is prolonged into an inner and an outer process. The bipolar cells are divisible into rod-bipolars and cone-bipolars. The inner processes of the *rod-bipolars* run through the inner plexiform layer and arborise around the outer parts of the cell-bodies of the ganglionic layer; their outer processes end in the outer plexiform

layer in tufts of fibrils around the button-like ends of the inner processes of the rod-granules. The inner processes of the *cone-bipolars* ramify in the inner plexiform layer in contact with the dendrites of the ganglionic cells.

The *horizontal cells* lie in the outer part of the inner nuclear layer and possess somewhat flattened cell-bodies. Their dendrites divide into numerous branches in the outer plexiform layer, while their axons run horizontally for some distance and finally ramify in the same layer.

The *amacrine cells* are placed in the inner part of the inner nuclear layer, and were so named under the supposition that they possessed no axons. It is now known that some, at least, possess axons. Their dendrites undergo extensive ramification in the inner plexiform layer.

5. The *outer plexiform layer* is much thinner than the inner; but, like it, consists of a dense network of minute fibrils derived from the processes of the horizontal cells, and the outer processes of the rod- and cone-bipolar cells of the preceding layer, which arborise around the enlarged ends of the rod-fibres and the branched foot-plates of the cone-fibres.

6. The *outer nuclear layer*.—Like the inner nuclear layer, this contains several strata of oval cells; they are of two kinds, viz. rod-granules and cone-granules, the former being connected with the rods, the latter with the cones, of the next layer. The *rod-granules* are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present in some animals a cross-striped appearance, and a fine process is prolonged from either extremity of each cell: the outer process is continuous with a single rod of the layer of rods and cones; the inner process ends in the outer plexiform layer in an enlarged extremity, and is imbedded in the tuft into which the outer processes of the rod-bipolar cells break up; in its course it presents numerous varicosities. The *cone-granules*, fewer in number than the rod-granules, are placed close to the *membrana limitans externa*, through which they are continuous with the cones of the layer of rods and cones. Each contains a spheroidal nucleus which almost completely fills the granule. From the inner extremity of each cone-granule a thick process passes into the outer plexiform layer, and there expands into a pyramidal enlargement or foot-plate, from which are given off numerous fine fibrils that come in contact with the outer processes of the cone-bipolars.

7. The *layer of rods and cones*.—The elements composing this layer are of two kinds, *rods* and *cones*, the former being much more numerous than the latter except in the macula lutea. The *rods* are cylindrical, of nearly uniform thickness, and are arranged perpendicularly to the surface. Each rod consists of two segments, an outer and an inner, of about equal lengths. The segments differ from each other as regards refraction and in their behaviour towards colouring reagents; the inner segment is stained by carmine, iodine, &c.; the outer segment is not stained by these reagents, but is coloured yellowish-brown by osmic acid. The outer segment is marked by transverse striæ, and tends to break up into a number of thin discs superimposed on one another; it also exhibits faint longitudinal markings. The inner part of the inner segment is indistinctly granular; the outer part presents a longitudinal striation, being composed of fine, highly refracting fibrils. The visual purple or rhodopsin is found only in the outer segments of the rods.

The *cones* are conical, their broad ends resting upon the *membrana limitans externa*, the narrow-pointed extremities being turned to the chorioid. Like the rods, each is made up of two segments, outer and inner; the outer segment is a short conical process, which, like the outer segment of a rod, exhibits transverse striæ. The inner segment resembles the inner segment of a rod in structure, presenting an outer striated and an inner granular part, but differs from it in size and shape, being flask-shaped. The optical characters of the two portions are identical with those of the rods.

Supporting framework of the retina.—The nervous layers of the retina are connected together by a supporting framework, formed by the *sustentacular fibres of Müller*; these fibres pass through all the nervous layers, except that of the rods and cones. Each fibre begins on the inner surface of the retina by an expanded, often forked, base, which sometimes contains a spheroidal body, staining deeply with hæmatoxylin; the edges of the bases of adjoining fibres are united to form the *membrana limitans interna*. As the fibres pass through the nerve-fibre and ganglionic layers they send off a few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the bipolar cells, while in the

outer nuclear layer they form a network around the rod- and cone-fibrils, and unite to form the *membrana limitans externa* at the bases of the rods and cones. At the level of the inner nuclear layer each sustentacular fibre contains a clear oval nucleus.

Structure of the macula lutea and fovea centralis.—At the fovea centralis there are no rods, and the cones are longer and thinner than in other parts of the retina. The nerve-fibre layer disappears at the margin of the fovea, and the other retinal layers are extremely thin. The pigment-cells are large and well-marked. At the circumference of the fovea the retina rapidly increases in thickness, so that this part of the macula lutea has a greater depth than any other part of the retina. All the layers are involved in this increase, but especially the ganglionic layer, in which the cells are six to eight deep. The yellow colour of the macula seems to imbue all the layers except that of the rods and cones; it is deepest towards the centre of the macula, and does not appear to be due to pigment-cells, but simply to a staining of the constituent parts.

At the *ora serrata* the nervous layers of the retina end abruptly, and the retina is continued onwards as a single layer of columnar cells along with the pigmented layer. This double layer is known as the *pars ciliaris retinae*, and can be traced forwards from the ciliary processes on to the back of the iris, where it is termed the *pars iridica retinae* or *uvea*.

The *arteria centralis retinae* (fig. 881) and its accompanying vein pierce the lower and medial aspect of the optic nerve, and enter the bulb of the eye through the porus opticus. The artery immediately bifurcates into an upper and a lower branch, and each of these again divides into a medial or nasal and a lateral or temporal branch, which at first run between the hyaloid membrane and the nervous layer; but they soon enter the latter, and pass forwards, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives two small branches (superior and inferior macular arteries) from the temporal branches, and small twigs directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no blood-vessels. The branches of the *arteria centralis retinae* do not anastomose with each other—in other words, they are terminal arteries. In the fœtus, a small vessel, the *arteria hyaloidea*, passes forwards as a continuation of the *arteria centralis retinae* through the vitreous humour to the posterior surface of the capsule of the lens.

REFRACTING MEDIA

The refracting media are three, viz. :

Aqueous humour.	Vitreous body.	Crystalline lens.
-----------------	----------------	-------------------

I. AQUEOUS HUMOUR

The aqueous humour fills the anterior and posterior chambers of the eyeball (p. 958). It is small in quantity, has an alkaline reaction, and is mainly a dilute watery solution of chloride of sodium. It is secreted by the ciliary processes into the posterior chamber and escapes from the filtration angle of the anterior chamber through the spaces of the angle of the iris (spaces of Fontana) and sinus venosus sclerae (canal of Schlemm) into the anterior ciliary veins.

II. VITREOUS BODY

The vitreous body occupies about four-fifths of the bulb of the eye. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, the *hyaloid fossa*, for the reception of the lens. It is transparent, of the consistence of thin jelly, and is enclosed in a delicate transparent membrane, the *hyaloid membrane*. It has been supposed by Hannover, that from the surface of the hyaloid membrane numerous thin lamellæ are prolonged inwards in a radiating manner, forming spaces in which the jelly is contained. In the adult, these lamellæ cannot be detected even after careful microscopical examination in the fresh state, but in preparations hardened in weak chromic acid it is possible to make out a distinct lamellation at the periphery of the vitreous body. Running forwards through the vitreous body from the entrance of the optic nerve to the posterior surface of the lens, is a canal, the *hyaloid canal*, filled with lymph and lined by a prolongation of the hyaloid membrane.

In the embryonic vitreous body this canal conveyed the arteria hyaloidea from the central artery of the retina to the back of the lens.

The fluid from the vitreous body is nearly pure water ; it contains, however, some salts, and a little albumin.

The *hyaloid membrane* envelops the vitreous body. The portion in front of the ora serrata is thickened by the accession of radial fibres and is termed the *zonula ciliaris* or *zonule of Zinn*. Here it presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they adhere, as is shown by the fact that when they are removed some of their pigment remains attached to the zonula. The zonula ciliaris splits into two layers, one of which is thin and lines the hyaloid fossa of the vitreous body ; the other, named the *suspensory ligament of the lens*, is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the meridional fibres of the Ciliaris muscle, so that the lens is allowed to become more convex. Behind the suspensory ligament there is a sacculated canal, the *spatia zonularia* or *canal of Petit*, which encircles the equator of the lens ; it can be easily inflated through a fine blowpipe inserted under the suspensory ligament.

No blood-vessels penetrate the vitreous body ; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. CRYSTALLINE LENS

The **crystalline lens**, enclosed in its capsule, is situated immediately behind the iris, in front of the vitreous body, and is encircled by the ciliary processes, which slightly overlap its margin.

The *capsule of the lens* is a transparent, structureless membrane which closely surrounds the lens, and is thicker in front than behind. It is brittle but highly elastic, and when ruptured the edges roll up with the outer surface innermost. The lens rests, behind, in the hyaloid fossa on the fore-part of the vitreous body ; in front, it is in contact with the free border of the iris, but recedes from it at the circumference, thus forming the posterior chamber of the eye ; it is retained in its position chiefly by the suspensory ligament already described.

The *lens* is a transparent, biconvex body, the convexity of its anterior being less than that of its posterior surface. The central points of these surfaces are termed respectively the *anterior* and *posterior poles* ; a line connecting the poles constitutes the *axis* of the lens, while the marginal circumference is termed the *equator*.

Structure.—The lens is made up of soft cortical substance and a firm, central part, the nucleus (fig. 885). Faint lines (*radii lentis*) radiate from the poles to the equator. In the adult there may be six or more of these lines, but in the fœtus there are only three, and these diverge from each other at angles of 120° (fig. 886) ; on the anterior surface one line ascends vertically and the other two diverge downwards ; on the posterior surface one ray descends vertically and the other two diverge upwards. They correspond with the free edges of an equal number of septa composed of an amorphous substance, which dip into the substance of the lens. When the lens has been hardened it is seen to consist of a series of concentrically arranged laminae, each of which is interrupted at the septa referred to. Each lamina is built up of a number of ribbon-like lens-fibres, the edges of which are more or less serrated—the serrations fitting between those of neighbouring fibres, while the ends of the fibres come into apposition at the septa. The fibres run in a curved manner from the septa on the anterior surface to those on the posterior surface. No fibres pass from pole to pole ; they are arranged in such a way that those which begin near the pole on one surface of the lens end

FIG. 885.—The crystalline lens, hardened and divided. (Enlarged.)

near the peripheral extremity of the plane on the other, and vice versa. The fibres of the outer layers of the lens are nucleated, and together form a nuclear layer, most distinct towards the equator. The anterior surface of the lens is covered by a layer of transparent, nucleated columnar epithelium. At the equator the cells become elongated, and their gradual transition into lens-fibres can be traced (fig. 888).

In the fetus, the lens is nearly spherical, and has a slightly reddish tint; it is soft, and breaks down readily on the slightest pressure. A small branch from the arteria centralis retinæ runs forwards, as already mentioned, through the

FIG. 886.—A diagram to show the direction and arrangement of the radiating lines on the front and back of the foetal lens. A. On the front. B. On the back.

vitreous body to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network which covers the posterior surface of the capsule, and they are continuous round the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. *In the adult*, the lens is colourless, transparent, firm in texture, and devoid of vessels. *In old age*, it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increased in density (fig. 887).

Vessels and Nerves.—The arteries of the bulb of the eye are the long, short, and anterior ciliary arteries, and the arteria centralis retinæ. They have already been described (p. 597).

The ciliary veins are seen on the outer surface of the chorioid, and are named, from their arrangement, the *venæ vorticose*; they converge to four or five equidistant trunks which pierce the sclera midway between the sclero-corneal junction and the porus opticus. Another set of veins accompanies the anterior ciliary arteries. All these veins open into the ophthalmic veins.

The ciliary nerves are derived from the nasociliary nerve and from the ciliary ganglion.

FIG. 887.—A profile view of the lens at different periods of life.

1. In the fetus. 2. In adult life. 3. In old age:

continuous with the epithelial covering of the rest of the body, so that its lesions resemble those of the epidermis; (2) the cornea proper, derived from the mesoderm, and associated in its diseases with the fibrovascular structures of the body; and (3) the posterior elastic lamina with its endothelium, also derived from the mesoderm and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the serous and synovial membranes of the body.

The cornea contains no blood-vessels except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on its anterior surface. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of the angle of the iris. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In cases of *granular lids*, there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea become vascularised, and a rich network of blood-vessels may be seen upon it; and in *interstitial keratitis* new vessels extend into the cornea, giving it a pinkish hue to which the term 'salmon patch' is

Applied Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) an external epithelial layer, developed from the ectoderm, and

applied. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the chorioid and sclera, the cornea becoming anæsthetic.

The sclera has very few blood-vessels and nerves. As the blood-vessels approach the corneal margin the arrangement is peculiar. Some branches pass through the sclera to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches by anastomosing with each other some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forwards to the cornea, forming its marginal plexus. In inflammation of the sclera and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the *zone of ciliary injection*. In inflammation of the iris and ciliary body this zone is present, since the sclera speedily becomes involved when these structures are inflamed. But in inflammation of the cornea the sclera is seldom much affected, though the two are structurally continuous. This would appear to be due to the fact, that the nutrition of the cornea is derived from a different source than that of the sclera. The sclera may be ruptured without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin. It may be complicated with lesions of adjacent parts—laceration of the chorioid, retina, iris, or suspensory ligament of the lens—and is then often attended with hæmorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclera. Wounds of the sclera are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia.

One of the functions of the chorioid is to provide nutrition for the retina, and to convey vessels and nerves to the ciliary body and iris. Inflammation of the chorioid is therefore followed by grave disturbances in the nutrition of the retina, and is attended with early interference with vision. Its diseases bear a considerable analogy to those which affect the skin, and it is one of the places from which melanotic sarcomata may grow. These tumours contain a large amount of pigment in their cells, and originate only in those parts where pigment is naturally present.

The iris may be absent, either in part or altogether, as a congenital condition, and in some instances the pupillary membrane may persist, though rarely as a complete structure. Again, the iris may be the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, clearly due in a great number of cases to an arrest in development. In these cases the cleft is found at the lower aspect, extending directly downwards from the pupil, and the gap frequently extends through the chorioid to the porus opticus. Wounds of the iris, especially if complicated with injury to the ciliary body, may be followed by serious consequences. If septic matter is introduced, and a suppurative inflammation is set up, complete loss of vision may result; and, what is perhaps of greater consequence, similar inflammatory changes may be set up in the sound eye. The iris is abundantly supplied with blood-vessels and nerves, and is very prone to become inflamed, and when inflamed, in consequence of the intimate relationship

which exists between the vessels of the iris and chorioid, this latter tunic is very liable to participate in the inflammation. The iris is covered with epithelium, and partakes of the character of a serous membrane, and like these structures, is apt to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens behind (*synechia posterior*). In iritis the lens may become involved, and the condition known as secondary cataract may be set up.

FIG. 888.—A section through the margin of the lens, showing the transition of the epithelium into the lens-fibres. (Babuchin.)

The retina, with the exception of its pigment layer and its vessels, is perfectly transparent. In retinitis there is more or less dense opacity of its structure, and not infrequently extravasations of blood into its substance. Hemorrhages may also take place into the retina, from rupture of a blood-vessel without inflammation. The retina may become detached from effusion of serum between it and the chorioid, or by blows on the eyeball; but detachment of the retina may occur without apparent cause in progressive myopia. Glioma, a form of sarcoma, is occasionally met with in the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. Opacities may occur from injury, senile changes, or malnutrition. These opacities give rise to *cataract*, of which the senile variety is the most common. They vary as to the part of the lens in which the opacity commences, and are classified accordingly, as nuclear, cortical, lamellar, anterior and posterior polar. Senile changes may take place in the lens, impairing its elasticity and rendering it harder than in youth, so that it loses its power of altering its curvature to suit the requirements of near vision. This condition is known as *presbyopia*. The lens may be dislocated or displaced by blows upon the eyeball; and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the 'filtration angle,' and the other as the 'dangerous area.' The *filtration angle* is the circumcorneal zone immediately in front of the iris. Here are situated the spaces of the angle of the iris, which communicate with the sinus venosus scleræ through which the chief transudation of fluid from the eye is believed to take place. If any obstruction to this transudation occur, increased intra-ocular tension is set up, and the disease known as *glaucoma* results. The *dangerous area of the eye* is the region in the neighbourhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is apt to spread to many of the other structures of the eye, especially to the iris and chorioid, which are intimately connected with it by nervous and vascular supplies.

ACCESSORY ORGANS OF THE EYE

The accessory organs of the eye include the ocular muscles, the fasciæ, the eyebrows, the eyelids, the conjunctiva, and the lacrimal apparatus.

OCULAR MUSCLES

The ocular muscles are the:

Levator palpebræ superioris.	Rectus medialis.
Rectus superior.	Rectus lateralis.
Rectus inferior.	Obliquus superior.
Obliquus inferior.	

The *Levator palpebræ superioris* (figs. 889, 890) is thin, flat, and triangular in shape. It arises from the under surface of the small wing of the sphenoid, above and in front of the optic foramen, from which it is separated by the origin of the Rectus superior. At its origin, it is narrow and tendinous, but soon becomes broad and fleshy, the medial margin of the muscle being almost straight, while the lateral margin curves towards the lateral canthus. The muscle ends anteriorly in a wide aponeurosis which splits into two lamellæ. The uppermost fibres of the superficial lamella blend with the upper part of the orbital septum; the lowermost fibres are attached to the anterior surface of the tarsus, while the intermediate fibres radiate and pass through the overlying Orbicularis oculi to the skin of the upper eyelid. The deep lamella consists of non-striped muscular fibres and is known as *Müller's muscle**; it is attached directly to the upper margin of the superior tarsus and is covered by conjunctiva on its inferior surface. The space between the superficial and deep lamellæ is termed the *preseptal space* (fig. 890).

The fascial sheaths of the Levator palpebræ superioris and Rectus superior fuse. Where the two muscles separate to reach their insertions, the fascia between them forms a thick mass which is fixed to the superior conjunctival fornix and is described as an additional insertion of the Levator palpebræ superioris. When traced laterally the

OCULAR MUSCLES

aponeurosis of the Levator palpebræ superioris passes between the upper and lower parts of the lacrimal gland, and is fixed to a tubercle on the zygomatic bone, just within the orbital margin (p. 234). Deep to this attachment is that of the lateral palpebral raphe

FIG. 889.—A sagittal section of the right orbital cavity.

which fixes the tarsal plates to the same tubercle. When traced medially the aponeurosis loses its tendinous nature as it passes over and comes into close contact with the reflected tendon of the Obliquus superior, whence it can be followed with difficulty towards the medial palpebral ligament in the form of loose strands of connective tissue. When the

* Levator palpebræ contracts, the lateral and medial parts of the aponeurosis are stretched and check the action of the muscle; the retraction of the upper eyelid is checked also by the orbital septum.*

* A. E. Whitnall, *Journal of Anatomy and Physiology*, vol. xiv., and *Ophthalmoscope*, May 1914.

The four Recti (fig. 891) arise from a fibrous ring (annulus tendineus communis) which surrounds the upper, medial, and lower margins of the optic foramen and encircles the optic nerve (fig. 892). The ring is completed by a tendinous bridge prolonged over the lower and medial part of the superior orbital fissure and attached to a tubercle on the margin of the great wing of the sphenoid bounding the fissure. Two specialised parts of this fibrous ring may be made out: a lower, the ligament or tendon of Zinn, which gives origin to the Rectus inferior, part of the Rectus medialis, and the lower head of origin of the Rectus lateralis; and an upper, sometimes termed the superior tendon of Lockwood, which gives origin to the Rectus superior, the rest of the Rectus medialis, and the upper head of the Rectus lateralis. Each muscle passes forward in the position implied by its name, to be inserted by a tendinous expansion into the sclera, about 6 mm. from the margin of the cornea. Between the two heads of the Rectus lateralis is a narrow interval, which transmits the two divisions of the oculomotor nerve, the nasociliary nerve, the abducent nerve, and the ophthalmic veins. Although these muscles present a common origin and are inserted in a similar manner into the sclera, there are certain

FIG. 891.—The muscles of the right orbit.

differences to be observed in them. The Rectus medialis is the broadest, the Rectus lateralis the longest, and the Rectus superior the thinnest and narrowest. The Rectus lateralis is inserted slightly further back than the Rectus medialis and Rectus superior.

The Obliquus oculi superior is a fusiform muscle, placed at the upper and medial side of the orbit. It arises immediately above the optic foramen, above and medially to the origin of the Rectus superior, and, passing forwards, ends in a rounded tendon, which plays in a fibrocartilaginous ring or pulley attached to the fovea trochlearis of the frontal bone. The contiguous surfaces of the tendon and ring are lined by a delicate mucous sheath, and enclosed in a thin fibrous investment. After passing through the pulley the tendon is reflected backwards, lateralwards, and downwards beneath the Rectus superior, to the lateral part of the bulb of the eye, and is inserted into the sclera, behind the equator of the eyeball, and between the Rectus superior and Rectus lateralis.

The Obliquus oculi inferior is a thin, narrow muscle, placed near the anterior margin of the floor of the orbit. It arises from the orbital surface of the maxilla laterally to the lacrimal groove. Passing lateralwards, backwards, and upwards, at first between the Rectus inferior and the floor of the orbit, and then between the bulb of the eye and the Rectus lateralis, it is inserted into the lateral part of the sclera between the Rectus superior and Rectus lateralis, near to, but somewhat behind, the insertion of the Obliquus superior.

Nerves.—The Levator palpebræ superioris, the Obliquus inferior, and the Recti superior, inferior, and medialis are supplied by the oculomotor nerve; the Obliquus superior, by the trochlear nerve; the Rectus lateralis, by the abducent nerve.

Actions.—The Levator palpebræ raises the upper eyelid, and is the direct antagonist of the Orbicularis oculi. The four Recti are attached to the bulb of the eye in such a manner that, acting singly, they will turn its corneal surface either upwards, downwards, medialwards, or lateralwards, as expressed by their names. The movement produced by the Rectus superior or Rectus inferior is not quite a simple one, for inasmuch as each passes obliquely lateralwards and forwards to the bulb of the eye, the elevation or depression of the cornea is accompanied by a certain deviation medialwards, with a slight amount of rotation. These latter movements are corrected by the Obliqui, the Obliquus inferior correcting the medial deviation caused by the Rectus superior, and the Obliquus superior that caused by the Rectus inferior. The contraction of the Rectus lateralis or Rectus medialis, on the other hand, produces a purely horizontal movement. If any two neighbouring Recti of

FIG. 892.—A dissection showing the origins of the right ocular muscles, and the nerves entering the orbit through the superior orbital fissure.

one eye act together they carry the globe of the eye in the diagonal of these directions, viz. upwards and medialwards, upwards and lateralwards, downwards and medialwards, or downwards and lateralwards. Sometimes the corresponding Recti of the two eyes act in unison, and at other times the opposite Recti act together. Thus, in turning the eyes to the right, the Rectus lateralis of the right eye will act in unison with the Rectus medialis of the left eye; but if both eyes are directed to an object in the middle line at a short distance, the two Recti mediales will act in unison. The movement of circumduction, as in looking round a room, is performed by the successive actions of the four Recti. The Obliqui rotate the bulb of the eye on its anteroposterior axis, the superior directing the cornea downwards and lateralwards, and the inferior directing it upwards and lateralwards; these movements are required for the correct viewing of an object when the head is moved laterally, as from shoulder to shoulder, in order that the picture may fall in all respects on the same part of the retina of either eye.

A layer of non-striped muscle, the *Orbitalis muscle* of H. Müller, bridges across the inferior orbital fissure.*

* The *Orbitalis muscle* of Müller must not be confused with the palpebral non-striped muscle described by him. In the upper eyelid this unites the superior tarsus to the tendon of the Levator palpebræ superioris; in the lower eyelid it connects the inferior tarsus with the Obliquus inferior (see p. 969).

The **fascia bulbi** (capsule of Tenon) (fig. 893) is a thin membrane which envelops the bulb of the eye from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is separated from the outer surface of the sclera by the *periscleral lymph-space*; this lymph-space is continuous with the subdural and subarachnoid cavities, and is traversed by delicate bands of connective tissue which extend between the fascia and the sclera. The fascia is perforated behind by the ciliary vessels and nerves, and fuses with the sheath of the optic nerve and with the sclera around the entrance of the optic nerve. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball. It is perforated by the tendons of the ocular muscles,

FIG. 893.—A sagittal section of the right eye, showing the fascia bulbi.
(Semi-diagrammatic.) (Testut.)

and is reflected backwards on each as a tubular sheath. The sheath of the Obliquus superior is carried as far as the fibrous pulley of that muscle; that on the Obliquus inferior reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the Recti are gradually lost in the perimysium, but they give off important expansions. The expansion from the Rectus superior blends with the tendon of the Levator palpebrae superioris; that of the Rectus inferior is attached to the inferior tarsus. The expansions from the sheath of the Recti medialis and lateralis are strong, especially that from the latter muscle, and are attached to the lacrimal and zygomatic bones respectively. As they probably check the actions of these two Recti they have been named the *medial and lateral check ligaments*. Lookwood* described a thickening of the lower part of the fascia bulbi, which he named the *suspensory ligament of the eye*; it is slung like a hammock below the eyeball, being expanded in the centre, and narrow at its extremities, which are attached to the zygomatic and lacrimal bones respectively.

* *Journal of Anatomy and Physiology*, vol. xx.

The orbital fascia forms the periosteum of the orbit, but is loosely connected to the bones. Behind, it is united with the dura mater and with the sheath of the optic nerve. In front, it is connected with the periosteum at the margin of the orbit, and sends off a stratum which assists in forming the orbital septum. From it two processes are given off: one to enclose the lacrimal gland, the other to hold the pulley of the Obliquus superior in position.

Applied Anatomy.—The positions and exact areas of insertion of the tendons of the Recti medialis and lateralis into the bulb of the eye should be carefully examined from the front, as the surgeon is often required to divide one or other of the muscles for the cure of strabismus. In convergent strabismus, which is the more common form of the disease, the eye is turned medialwards, which may require the division of the Rectus medialis. In the divergent form, which is more rare, the eye is turned lateralwards, the Rectus lateralis being especially implicated. If the deformity produced in either case be marked, it may be remedied by division of one or the other muscle. The operation is thus performed: the lids are to be well separated; the eyeball is rotated lateralwards or medialwards, and the conjunctiva raised by a pair of forceps, and incised immediately beneath the lower border of the tendon of the muscle to be divided, a little behind its insertion into the sclera; the submucous areolar tissue is then divided, and into the small aperture thus made, a blunt hook is passed upwards between the muscle and the bulb, and the tendon of the muscle divided by a pair of blunt-pointed scissors passed between the hook and the bulb.

The converse operation is that of *advancement*, in which either the Rectus medialis or Rectus lateralis (depending on the form of strabismus) is shortened. The muscle is exposed in a similar manner; its tendon is divided, and sutured to the globe of the eye in front of its previous site of attachment.

Removal of the eyeball is effected by dividing the conjunctiva all round with scissors at its attachment to the cornea, after which each ocular muscle in turn is picked up on a blunt hook and divided close to the sclera. The optic nerve is then divided with curved scissors passed to the back of the orbit; it should be remembered that the perineural sheaths from the meninges are opened by this manœuvre.

Exophthalmos, or abnormal protrusion of the eyeball, is usually bilateral. It is almost always present in exophthalmic goitre or Graves' disease, in which it is due to abnormal stimulation of the cervical sympathetic nerves producing spasm of Müller's muscle, which passes between the eyeball and the eyelids. Less often it results from venous congestion of the orbital veins due to thrombosis of the cavernous sinuses. Unilateral exophthalmos is rare, and is caused by orbital cellulitis, periostitis, or new growth, or by traumatic arterial or arteriovenous aneurysm of the carotid artery behind the orbit. Intermittent exophthalmos, occurring only when the head is depressed, is very rare, and is due to the presence of varicose veins in the orbit.

In hydrocephalus the eyeball may be forced down so low in the orbit, through depression of the orbital plate of the frontal bone by the accumulation of fluid within the brain, that the patient, usually an infant, loses his sight because the pupil comes to lie below the lower eyelid even when the eye is open.

The eyebrows are two arched eminences of skin, which surmount the orbits, and support numerous short, thick hairs directed obliquely on the surface. Fibres of the Orbicularis oculi, Corrugator, and Frontalis muscles are inserted into the skin of the eyebrows.

The eyelids or palpebræ are two thin, movable folds, placed in front of the eye, protecting it from injury by their closure. The upper eyelid is the larger and more movable, and is furnished with an elevator muscle, the Levator palpebræ superioris. When the eyelids are open, an elliptical space, the palpebral fissure (*rima palpebrarum*) is left between their margins, the angles

FIG. 894.—The front of the left eye with the eyelids separated to show the plica semilunaris, caruncula lacrimalis and puncta lacrimalia.

of which correspond to the junctions of the upper and lower eyelids, and are called the *palpebral commissures* or *canthi*.

The *lateral palpebral commissure* is more acute than the medial, and the eyelids here lie in close contact with the bulb of the eye: but the *medial palpebral commissure* is prolonged for a short distance towards the nose, and the two eyelids are separated by a triangular space, the *lacus lacrimalis* (fig. 894). At the basal angles of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the *lacrimal papilla*, the apex of which is pierced by a small orifice, the *punctum lacrimale*, the commencement of the lacrimal duct.

The *eyelashes* are attached to the free edges of the eyelids from the lateral palpebral commissure to the lacrimal papillæ. They are short, thick, curved

FIG. 895.—A sagittal section through the upper eyelid. (After Waldeyer.)

a. Skin. b. Orbicularis oculi. b'. Marginal fasciculus of Orbicularis (ciliary bundle). c. Levator palpebræ. d. Conjunctiva. e. Tarsal glands. f. Opening of tarsal gland. g. Sebaceous gland. h. Eyelashes. i. Small hairs of skin. j. Sweat-glands. k. Posterior tarsal glands.

hairs, arranged in double or triple rows: those of the upper eyelid, more numerous and longer than those of the lower, curve upwards; those of the lower eyelid curve downwards, so that the upper and lower eyelashes do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of a number of glands, the *ciliary glands*, arranged in several rows close to the free margin of each lid; they are regarded as enlarged and modified sudoriferous glands.

Structure of the eyelids.—From without inwards, each eyelid consists of: skin, areolar tissue, fibres of the Orbicularis oculi, tarsus, orbital septum, tarsal glands and conjunctiva. The upper eyelid has, in addition, the aponeurosis of the Levator palpebræ superioris (fig. 895).

The *skin* is extremely thin, and continuous at the margins of the eyelids with the conjunctiva.

The *subcutaneous areolar tissue* is very lax and delicate, and seldom contains any fat.

The *palpebral fibres of the Orbicularis oculi* are thin, pale in colour, and parallel to the palpebral fissure.

The *tarsi* (fig. 896) are two thin elongated plates of dense connective tissue, about 2.5 cm. in length; one is placed in each eyelid, and contributes to its form and support. The *superior tarsus*, the larger, is of a semilunar form, about 10 mm. in height at the centre, and gradually narrowing towards its extremities.

The lowest fibres of the superficial

lamella of the aponeurosis of the Levator palpebræ superioris are attached to the anterior surface, and the deep lamella of the same aponeurosis is inserted into the upper margin, of the superior tarsus. The *inferior tarsus*, the smaller, is thin, fairly uniform in breadth, and has a vertical diameter of about 5 mm. The free or ciliary margins of these plates are thick and straight. The attached or orbital margins are connected to the circumference of the orbit by the orbital septum. The lateral angles are attached to the zygomatic bone by the lateral palpebral raphe. The medial angles of the two plates end at the lacus lacrimalis, and are attached to the frontal process of the maxilla by the medial palpebral ligament (p. 429).

The *orbital septum* is a membranous sheet, attached to the edge of the orbit, where it is continuous with the periosteum. In the upper eyelid it blends with the aponeurosis of the Levator palpebræ superioris, and in the lower eyelid with the inferior tarsus. It is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

FIG. 896.—The tarsi and their ligaments. Front view. (Testut.)

The *tarsal glands* (Meibomian glands) (fig. 897) are situated near the inner surfaces of the eyelids, between the tarsi and conjunctiva, and may be distinctly seen through the latter on everting the eyelids, presenting an appearance like parallel strings of pearls. There are about thirty in the upper eyelid, and somewhat fewer in the lower. They are imbedded in grooves in the inner surfaces of the

FIG. 897.—The tarsal glands of the eyelids. Seen from within.

tarsi and correspond in length with the breadth of these plates; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margins of the lids by minute foramina.

Structure.—The tarsal glands are modified sebaceous glands, each consisting of a single straight tube or follicle, with numerous small lateral diverticula. The tubes are supported by a basement membrane, and are lined at their mouths by stratified epithelium; the deeper parts of the tubes and the lateral offshoots are lined by a layer of polyhedral cells.

The *conjunctiva* is the mucous membrane of the eye. It lines the inner surfaces of the eyelids or palpebræ, and is reflected over the fore part of the sclera and the cornea.

The *palpebral portion* is thick, opaque, highly vascular, and has numerous subepithelial connective tissue papillæ, its deeper part containing a considerable amount of lymphoid tissue. At the margins of the lids it is continuous with the lining membranes of the ducts of the tarsal glands, and, through the lacrimal ducts, with the lining membrane of the lacrimal sac and nasolacrimal duct. At the lateral angle of the upper eyelid the ducts of the lacrimal gland open on its free surface; and at the medial angle it forms a semilunar fold, the *plica semilunaris*. The line of reflection of the conjunctiva from the upper eyelid on to the bulb of the eye is named the *superior fornix*, and that from the lower lid the *inferior fornix*; on account of the greater size of the upper eyelid the superior fornix appears to be situated further back than the inferior. Upon the *sclera* the conjunctiva is loosely connected to the bulb of the eye; it is thin, transparent, destitute of papillæ, and only slightly vascular. Upon the *cornea*, the conjunctiva consists only of epithelium, constituting the epithelium of the cornea, already described (p. 954). The epithelium of the palpebral conjunctiva is columnar, that of the corneal conjunctiva and the cornea is stratified squamous. *Lymphatics* arise in a delicate zone around the cornea, and run to the ocular conjunctiva.

In and near the fornices, but more plentiful in the upper than in the lower eyelid, a number of convoluted tubular glands open on the surface of the conjunctiva. Other glands, analogous to lymphoid follicles, and called by Henle *trachoma glands*, are found in the conjunctiva, and, according to Stromeyer, are chiefly situated near the medial palpebral commissure. They were first described by Brush, in his description of Peyer's patches of the small intestine, as 'identical structures existing in the under eyelid of the ox.'

The *caruncula lacrimalis* (fig. 894) is a small, reddish, conical body situated at the medial palpebral commissure, and filling up the *lacus lacrimalis*. It consists of a small island of skin containing sebaceous and sudiferous glands, and is the source of the whitish secretion which constantly collects in this region. A few slender hairs are attached to its surface. Lateral to the caruncula is a slight semilunar fold of conjunctiva, the concavity of which is directed towards the cornea; it is called the *plica semilunaris*. Müller found smooth muscular fibres in this fold; in some of the domesticated animals it contains a thin plate of cartilage.

The nerves of the conjunctiva are numerous; many of them end in terminal bulbs, first described by Krause (p. 1005).

LACRIMAL APPARATUS (fig. 898)

The lacrimal apparatus consists of (a) the lacrimal gland which secretes the tears, and its excretory ducts which convey the fluid to the surface of the eye; (b) the lacrimal ducts, the lacrimal sac, and the nasolacrimal duct, by which the fluid is conveyed into the cavity of the nose.

The *lacrimal gland* is lodged in the lacrimal fossa, on the medial side of the zygomatic process of the frontal bone. It is of an oval form, about the size and shape of an almond, and consists of two portions, described as the superior and inferior lacrimal glands. The *superior lacrimal gland* is connected to the periosteum of the orbit by a few fibrous bands; the *inferior lacrimal gland* is separated from the superior by the aponeurosis of the Levator palpebræ superioris, and projects into the back part of the upper eyelid, where its deep surface is related to the conjunctiva. The ducts of the glands, from six to twelve in number, run obliquely beneath the conjunctiva for a short distance, and open along the lateral half of the superior conjunctival fornix.

Structure of the lacrimal gland (fig. 899).—In structure and general appearance the lacrimal resembles the salivary glands (p. 1053). It is a compound *racemose gland*, the alveoli of which are lined by columnar cells resting on a basement membrane. The cells contain oval nuclei, and in the resting condition are crowded with small clear vacuoles, which disappear when the gland secretes actively; protoplasmic granules are also present. The ducts are lined by columnar epithelial cells which do not show the rod-like structure of the corresponding cells in the salivary glands.

The lacrimal ducts or canals, one in each eyelid, commence as minute orifices, termed *puncta lacrimalia*, on the summits of the *papillae lacrimales*, seen on the margins of the lids at the lateral extremity of the lacus lacrimalis.

FIG. 898.—The lacrimal apparatus. Left side.

The *superior duct*, the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes medialwards and downwards to the lacrimal sac. The *inferior duct* at first descends, and then runs almost horizontally to the lacrimal sac. At the angles they are dilated into *ampullae*; their walls are dense in structure and their mucous lining is covered by stratified squamous epithelium, placed on a basement membrane. Outside the latter is a layer of striped muscle, continuous with the lacrimal part of the Orbicularis oculi; at the base of each lacrimal papilla the muscular fibres are circularly arranged and form a kind of sphincter.

The lacrimal sac is the upper dilated end of the nasolacrimal duct, and is lodged in a deep groove formed by the lacrimal bone and frontal process of the maxilla. It is oval in form and measures from 12 to 15 mm. in

length; its upper end is closed and rounded; its lower is continued into the nasolacrimal duct; in its lateral wall are the openings of the lacrimal ducts.

Relations.—The lacrimal sac is intimately related to the medial palpebral ligament which extends from the medial ends of the tarsal plates of the eyelids and

FIG. 899.—A transverse section of a portion of the lacrimal gland of a cat. $\times 250$.

divides into a strong anterior, and a weak posterior, lamina. The anterior lamina, the medial palpebral ligament (*tendo oculi*), passes in front of the upper part of the lacrimal sac and is attached to the anterior lacrimal crest and to the frontal process of the maxilla, anterior to this crest. This lamina is connected to the upper part of the lacrimal sac, but is separated from the lower part by some fibres of the *Orbicularis oculi* which pass deep to it, thus leaving its lower margin free and conspicuous after removal of the skin. The posterior lamina of the medial palpebral ligament passes behind and is adherent to the lacrimal sac and is attached to the posterior lacrimal crest; the lacrimal part of the *Orbicularis oculi* is also behind the sac.

The lower half of the fossa which lodges the lacrimal sac is related medially with the anterior part of the middle meatus of the nasal cavity; the upper half with the anterior ethmoidal cells.

S. B. Whitnall * examined 100 skulls and found that in 14 per cent. the anterior ethmoidal cells came into relation only with the posterior wall of the fossa; in 32 per cent. they reached as far forward as the suture between the lacrimal bone and the maxilla; while in 54 per cent. one large irregular cell extended forward as far as the anterior lacrimal crest.

Structure.—The lacrimal sac consists of a fibrous elastic coat, lined internally by mucous membrane; the latter is continuous, through the lacrimal ducts, with the conjunctiva, and through the nasolacrimal duct with the mucous membrane of the nasal cavity. The tears pass from the superolateral to the inferomedial angle of the conjunctival sac. They are directed by: (a) the medialward pull of the *Orbicularis oculi*; (b) the contractions of the muscle around the lacrimal ducts; and (c) the compression of the lacrimal sac by the lacrimal part of the *Orbicularis oculi*.

The **nasolacrimal duct** (nasal duct) is a membranous canal, about 18 mm. long, which extends from the lower part of the lacrimal sac to the anterior part of the inferior meatus of the nose, where it ends in a somewhat expanded orifice, provided with an imperfect valve, the *plica lacrimalis* (*Hasneri*), formed by a fold of the mucous membrane. It is contained in an osseous canal, formed by the maxilla, the lacrimal bone, and the inferior nasal concha; it is narrower in the middle than at either end, and is directed downwards, backwards, and a little lateralwards. The mucous lining of the lacrimal sac and nasolacrimal duct is covered with columnar epithelium which in places is ciliated.

Applied Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin covering them is thin and delicate, and is supported on a quantity of loose areolar subcutaneous tissue, devoid of fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighbouring cicatrices, and thus produces an eversion of the lid, known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the *Orbicularis oculi* or from chronic inflammation of the palpebral conjunctiva may also occur. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue, the extravasation of blood may be so great as to produce considerable swelling of the eyelids and complete closure of the eye, and the same is the case when inflammatory products are poured out. The follicles of the eyelashes, or the sebaceous glands associated with these follicles, may be the seat of inflammation, constituting the ordinary 'stye.' Irregular or disorderly growth of the eyelashes not infrequently occurs, some of them being turned towards the eyeball and producing inflammation and ulceration of the cornea, and possibly eventually complete destruction of the eye. The *Orbicularis oculi* may be the seat of spasm, either in the form of slight quivering of the lids; or repeated twitchings, most commonly due to errors of refraction in children; or more continuous spasms, due to some irritation of the trigeminal or of the facial nerve. The *Orbicularis oculi* may be paralysed with the other facial muscles. Under these circumstances the patient is unable to close the lids, and, if he attempts to do so, rolls the eyeball upwards under the upper eyelid. The tears overflow from displacement of the lower eyelid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. Ptosis, or drooping of the upper eyelid, may be congenital, or may be due to paralysis of the *Levator palpebræ superioris*, in which case there will probably be other symptoms of implication of the oculomotor nerve. The eyelids may be the seat of bruises, wounds, or burns. Following burns, adhesion of the margins of the lids to each other, or adhesion of the lids to the bulb may take place. They are sometimes the seat of emphysema, after fracture of some of the thin bones forming the medial wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostril through the lacerated structures

into the connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling characteristic of this affection.

Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface, during the movements of the eyelids and the eye on each other. The conjunctiva is often involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a burn, either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclera, which is present in inflammation of the deeper structures of the bulb of the eye. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off towards the corneal margin; they anastomose freely and form a dense network, and they can be emptied or displaced by gentle pressure. Inflammation of the underlying sclera, ciliary body, or iris, is a far more serious condition; the injection is in the deeper vessels of the eye, and as seen through the sclera presents a diffuse and dull purplish or violet zone of circumcorneal discoloration.

The lacrimal ducts may become occluded as a result of burns or injury; overflow of the tears may also result from deviation of the puncta, or from chronic inflammation of the lacrimal sac. This latter condition is set up by some obstruction to the nasolacrimal duct, frequently associated with some infection from the nasal cavity. In consequence of this the tears and mucus accumulate in the lacrimal sac and distend it. Suppuration in the lacrimal sac is sometimes met with: this may be the sequel of a chronic inflammation. It may lead to lacrimal fistula from an abscess forming in the sac, which bursts or is opened on the surface: the condition is often seen in badly nourished, tuberculous children.

THE ORGAN OF HEARING

The ear or organ of hearing is divisible into three parts: the external ear, the middle ear or tympanic cavity, and the internal ear or labyrinth.

THE EXTERNAL EAR

The **external ear** consists of the expanded portion named the *auricula* or *pinna*, and the *external acoustic meatus*. The former projects from the side of the head and serves to collect the vibrations of the air by which sound is produced; the latter leads inwards from the bottom of the auricula and conducts the vibrations to the tympanic cavity.

FIG. 900.—The right auricula. Lateral surface.

The **auricula** or **pinna** (fig. 900) is of an oval form, with its larger end directed upwards. Its lateral surface is irregularly concave, looks slightly forwards, and presents numerous eminences and depressions to which names have been assigned. The prominent rim of the auricula is called the *helix*; where the helix turns downwards behind, a small tubercle, the *auricular tubercle of Darwin*, is frequently seen; this tubercle is very evident about the sixth month of foetal life, when the whole auricula has a close resemblance to that of some of the adult monkeys. Another curved prominence, parallel with and in front of the helix, is called the *antihelix*; this divides above into two crura, between which is a triangular depression, the *fossa triangularis*. The narrow curved depression between the helix and the antihelix is called the *scapha*; the antihelix describes a curve round a deep, capacious cavity, the *concha*, which is incompletely divided into two parts by the *crus* or anterior end of the helix; the upper part is termed the *cymba conchae*, the lower part the *caelum conchae*. In front of the concha, and projecting backwards over the meatus, is a small pointed eminence, the *tragus*: so called from its being

generally covered on its under surface with a tuft of hair, resembling a goat's beard. Opposite the tragus, and separated from it by the *intertragic notch*, is a small tubercle, the *antitragus*. Below this is the *lobule*, composed of tough

FIG. 901.—The cranial surface of the cartilage of the right auricle.

areolar and adipose tissues, and wanting the firmness and elasticity of the rest of the auricle.

The cranial surface of the auricle presents elevations which correspond to the depressions on its lateral surface, and after which they are named, e.g. eminentia conchæ, eminentia triangularis, &c.

FIG. 902.—The muscles of the auricle.

Structure.—The auricle is composed of a thin plate of yellow fibrocartilage, covered with skin, and connected to the surrounding parts by ligaments and muscles; it is continuous with the cartilaginous portion of the external acoustic meatus, and the latter is joined to the circumference of the porus acusticus externus by fibrous tissue.

The *skin* is thin, closely adherent to the cartilage, and covered with fine hairs furnished with sebaceous glands which are most numerous in the concha and scaphoid fossa. On the tragus and antitragus the hairs are strong and numerous. The skin of the auricle is continuous with that lining the external acoustic meatus.

The *cartilage of the auricle* (figs. 901, 902) consists of a single piece; upon its surface are found the eminences and depressions above described.

It is absent from the lobule; it is deficient, also, between

the tragus and beginning of the helix, the gap being filled up by dense fibrous tissue. At the front part of the auricle, where the helix bends upwards, is a small projection of cartilage, called the *spina heliciis*, while in the lower part of the helix the cartilage is prolonged downwards as a tail-like process.

the *cauda heliis*; this is separated from the antihelix by a fissure, the *fissura antitragohelicina*. The cranial aspect of the cartilage exhibits a transverse furrow, the *sulcus antiheliciis transversus*, which corresponds with the inferior crus of the antihelix and separates the eminentia conchæ from the eminentia triangularis. The eminentia conchæ is crossed by a vertical ridge (*ponticulus*) which gives attachment to the Auricularis posterior muscle. In the cartilage of the auricula are two fissures, one behind the crus heliis and another in the tragus.

The ligaments of the auricula consist of two sets: (1) extrinsic, connecting it to the side of the head; (2) intrinsic, connecting various parts of its cartilage together.

The extrinsic ligaments are two in number, anterior and posterior. The anterior ligament extends from the tragus and spina heliis to the root of the zygomatic process of the temporal bone. The posterior ligament passes from the posterior surface of the concha to the outer surface of the mastoid process.

The chief intrinsic ligaments are: (a) a strong fibrous band, stretching from the tragus to the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (b) a band between the antihelix and the cauda heliis. Other less important bands are found on the cranial surface of the pinna.

The muscles of the auricula (fig. 902) consist of two sets: (1) the extrinsic, which connect it with the skull and scalp and move the auricula as a whole; and (2) the intrinsic, which extend from one part of the auricula to another.

The extrinsic muscles are the Auriculares anterior, superior, and posterior.

The Auricularis anterior, the smallest of the three, is thin, fan-shaped, and its fibres are pale and indistinct. It arises from the lateral edge of the galea aponeurotica, and its fibres converge to be inserted into the spina heliis.

The Auricularis superior, the largest of the three, is thin and fan-shaped. Its fibres arise from the galea aponeurotica, and converge to be inserted by a thin, flattened tendon into the upper part of the cranial surface of the auricula.

The Auricularis posterior consists of two or three fleshy fasciculi, which arise by short aponeurotic fibres from the mastoid portion of the temporal bone, and are inserted into the lower part of the cranial surface of the concha.

Actions.—In man, these muscles possess very little action: the Auricularis anterior draws the auricula forwards and upwards; the Auricularis superior slightly raises it; and the Auricularis posterior draws it backwards.

The intrinsic muscles are the:

Helicis major.

Antitragicus.

Helicis minor.

Transversus auriculæ.

Tragicus.

Obliquus auriculæ.

The *Helicis major* is a narrow vertical band situated upon the anterior margin of the helix. It arises from the spina heliis, and is inserted into the anterior border of the helix, just where it is about to curve backwards.

The *Helicis minor* is an oblique fasciculus, covering the crus heliis.

The *Tragicus* is a short, flattened vertical band on the lateral surface of the tragus.

The *Antitragicus* arises from the outer part of the antitragus, and is inserted into the cauda heliis and antihelix.

The *Transversus auriculæ* is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendinous and partly muscular, extending from the eminentia conchæ to the eminentia scaphæ.

The *Obliquus auriculæ*, also on the cranial surface, consists of a few fibres extending from the upper and back part of the eminentia conchæ to the eminentia triangularis.

Nerves.—The Auriculares anterior and superior, and the intrinsic muscles on the lateral surface, are supplied by the temporal branches of the facial nerve, the Auricularis posterior and the intrinsic muscles on the cranial surface by the posterior auricular branch of the same nerve.

The arteries of the auricula are: (a) the posterior auricular branch of the external carotid artery, which supplies three or four branches to the cranial surface; from these branches twigs reach the lateral surface, partly by passing through the fissures of the auricular cartilage, and partly by turning round the margin of the helix; (b) the anterior auricular branches of the superficial temporal artery, which are distributed to the lateral surface; and (c) a branch from the occipital artery.

The veins accompany the corresponding arteries.

The sensory nerves are: the great auricular nerve, from the cervical plexus; the auricular branch of the vagus nerve; the auriculotemporal branch of the mandibular nerve; and the lesser occipital nerve from the cervical plexus.

The external acoustic meatus extends from the bottom of the concha to the tympanic membrane (figs. 903, 904). It is about 4 cm. long if measured from the tragus; from the bottom of the concha its length is about 2.5 cm.

It forms an S-shaped curve, and is directed at first inwards, forwards, and slightly upwards (*pars externa*) ; it then passes inwards and backwards (*pars media*), and lastly is carried inwards, forwards, and slightly downwards (*pars interna*). It is an oval cylindrical canal, the greatest diameter being directed downwards and backwards at the external orifice, but nearly horizontally at the inner end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, named the *isthmus*, in the osseous portion, about 2 cm. from the bottom of the concha. The tympanic membrane, which closes the inner end of the meatus, is obliquely directed ; in consequence of this obliquity the floor and anterior wall of the meatus are longer than the roof and posterior wall.

The external acoustic meatus is formed partly by cartilage and membrane, and partly by bone, and is lined by skin.

FIG. 903.—The external and middle portions of the ear, opened from the front.
Right side.

The *cartilaginous portion* is about 8 mm. long; it is continuous with the cartilage of the auricula, and is fixed to the circumference of the porus acusticus externus of the temporal bone. The cartilage is deficient at the upper and posterior parts of the meatus, its place being supplied by fibrous membrane; two or three deep fissures are present in the anterior part of the cartilage.

The *osseous portion* is about 16 mm. long, and is narrower than the cartilaginous portion. It is directed inwards and a little forwards, forming in its course a slight curve the convexity of which is upwards and backwards. Its inner end is smaller than the outer, and sloped, the anterior wall projecting beyond the posterior for about 4 mm.; this end is marked, except at its upper part, by a narrow groove, the *tympanic sulcus*, to which the circumference of the tympanic membrane is attached. Its outer end (*porus acusticus externus*) is dilated and rough in the greater part of its circumference, for the attachment of the cartilaginous portion. The anterior and inferior parts of the osseous portion are formed by the tympanic part of the temporal bone, which, in the fœtus, exists as the tympanic ring (p. 210).

The skin which envelops the auricula is continued into the external acoustic meatus and covers the outer surface of the tympanic membrane. It is thin and closely adherent to the cartilaginous and osseous parts of the tube. After

maceration, the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous *ceruminous glands* which secrete the ear-wax; their structure resembles that of the sudoriferous glands.

Relations of the meatus.—In front of the osseous part is the condyle of the mandible, which, however, is sometimes separated from the cartilaginous part by a small portion of the parotid gland. The movements of the mandible influence to some extent the lumen of this latter portion. Above the osseous part is the middle fossa of the skull; behind it are the mastoid air-cells, separated from the meatus by a thin layer of bone.

The *arteries* supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal arteries.

The *nerves* are chiefly derived from the auriculotemporal branch of the mandibular nerve and the auricular branch of the vagus nerve.

Applied Anatomy.—Malformations, such as imperfect development of the external parts, supernumerary auriculae, or absence of the meatus, are occasionally met with. The skin of the auricula is thin and richly supplied with blood, but in spite of this it is

FIG. 904.—A horizontal section through the left ear. Upper half of the section.

often the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*hematoma auris*), usually the result of traumatism, but not necessarily due to this cause; it is said to occur most frequently in the ears of the insane. Deposits of urate of soda are often met with in the auriculae of gouty subjects.

The external acoustic meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum, when the greater part of the canal and tympanic membrane can be brought into view. In using this instrument, it is advisable that the auricula should be drawn upwards, backwards, and a little outwards, so as to render the meatus as straight as possible. The points to be noted are: the presence of wax or foreign bodies; the size of the meatus; and the condition of the tympanic membrane. Accumulation of wax is often a cause of deafness, and may give rise to very serious consequences, such as ulceration of the membrane; it is best removed by syringing. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the meatus, may be removed with tolerable facility by means of a minute hook or loop of fine wire, aided by reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in no wise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the tympanic membrane and possibly the contents of the tympanic cavity.

At the point of junction of the osseous and cartilaginous portions an obtuse angle, which projects into the tube at its antero-inferior wall, is formed; this produces a sort of constriction, and renders it a narrow portion of the meatus—an important point to be

remembered in connexion with the presence of foreign bodies in the meatus. The shortness of the meatus in children should be borne in mind in introducing the aural speculum, so that it be not pushed in too far, at the risk of injuring the tympanic membrane; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. Just in front of the membrane is a well-marked depression, situated on the floor of the meatus, and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, or, timed with traction of the auricle upwards and backwards, the greater part of the tympanic membrane is rendered visible (fig. 905). It is a pearly-grey membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about fifty-five degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upwards, is a reddish-yellow streak; this is the handle of

FIG. 905.—The right tympanic membrane, as seen through a speculum.

the malleus, which is inserted into the membrane. At the upper part of this streak, close to the roof of the meatus, a little white, rounded prominence is plainly to be seen; this is the lateral or short process of the malleus, projecting against the membrane. The tympanic membrane does not present a plane surface; on the contrary, its centre is drawn inwards, on account of its connexion with the manubrium of the malleus, and thus the external surface is rendered concave.

The connexions of the nerves of the meatus explain the occurrence of constant coughing and sneezing, from implication of the vagus, when there exists any source of irritation in the meatus; and the vomiting which may follow syringing the ears of children, and the occasional heart failure similarly induced in elderly people. No doubt also the association of earache with toothache or with cancer of the tongue is due to implication of the mandibular branch of the trigeminal nerve, which supplies also the teeth and the tongue. The upper half of the tympanic membrane is much more vascular than the lower half; for this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

THE MIDDLE EAR, OR TYMPANIC CAVITY

The middle ear, or tympanic cavity, is an irregular, laterally compressed space within the temporal bone. It is filled with air, which is conveyed to it from the nasal part of the pharynx through the auditory tube. It contains a chain of movable bones, which connect its lateral to its medial wall, and transmit the vibrations of the tympanic membrane across the cavity to the internal ear.

The tympanic cavity consists of two parts: the *tympanic cavity proper*, opposite the tympanic membrane, and the *attic* or *epitympanic recess*, above the level of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. Including the attic, the vertical and antero-posterior diameters of the cavity are each about 15 mm. The transverse diameter measures about 6 mm. above and 4 mm. below; opposite the centre of the tympanic membrane it is only about 2 mm. The tympanic cavity is bounded laterally by the tympanic membrane; medially, by the lateral wall

of the internal ear; it communicates, behind, with the tympanic antrum and through it with the mastoid air-cells, and in front with the auditory tube (fig. 903).

The tegmental wall or roof of the tympanic cavity is formed by a thin plate of bone, the *tegmen tympani*, which separates the cranial and tympanic cavities and forms the greater part of the anterior surface of the petrous portion of the temporal bone; it is prolonged backwards so as to roof the tympanic antrum, and forwards to cover the semicanal for the Tensor tympani muscle.

The jugular wall or floor is narrow, and consists of a thin plate of bone (*fundus tympani*) which separates the tympanic cavity from the jugular fossa. In it, near the labyrinthine wall, is a small aperture for the passage of the tympanic branch of the glossopharyngeal nerve.

The membranous or lateral wall of the tympanic cavity is formed mainly by the tympanic membrane, but partly by the ring of bone in which this membrane is attached. There is a deficiency or notch in the upper part of the ring (*notch of Rivinus*), close to which are three small apertures, viz.: the *iter chordæ posterius*, the petrotympanic fissure, and the *iter chordæ anterior*.

The *iter chordæ posterius* (apertura tympanica canaliculi chordæ) is situated in the angle of junction between the mastoid and membranous walls of the tympanic cavity, immediately behind the tympanic membrane and on a level with the upper end of the manubrium mallei; it leads into a minute canal, which descends in front of the canal for the facial nerve, and ends in that canal about 6 mm. above the stylomastoid foramen. Through it the chorda tympani nerve and a branch of the stylo-mastoid artery enter the tympanic cavity.

The *petrotympanic fissure* (Gla-serian fissure) opens just above and in front of the ring of bone into which the tympanic membrane is inserted; in this situation it is a mere slit about 2 mm. in length. It lodges the anterior process and anterior ligament of the malleus, and transmits to the tympanic cavity the anterior tympanic branch of the internal maxillary artery.

The *iter chordæ anterior* (canal of Huguier) is placed at the medial end of the petrotympanic fissure; through it the chorda tympani nerve leaves the tympanic cavity.

The tympanic membrane (figs. 905, 906) separates the tympanic cavity from the bottom of the external acoustic meatus. It is a thin, semitransparent membrane, nearly oval in form, somewhat broader above than below, and placed very obliquely, forming an angle of about fifty-five degrees with the floor of the meatus. Its longest diameter is downwards and forwards, and measures from 9 to 10 mm.; its shortest diameter from 8 to 9 mm. The greater part of its circumference is thickened, and forms a *fibrocartilaginous ring* which is fixed in the *tympanic sulcus* at the inner end of the meatus. This sulcus is deficient superiorly at the notch of Rivinus, and from the ends of this notch two bands, the *anterior and posterior malleolar folds*, are prolonged to the lateral process of the malleus. The small, somewhat triangular part of the membrane

situated above these folds is lax and thin, and is named the *pars flaccida* (membrane of Shrapnell); a small orifice is sometimes seen in it. The chief part of the membrane is taut and is named the *pars tensa*. The manubrium of the malleus is firmly attached to the medial surface of the tympanic membrane as far as its centre, which it draws towards the tympanic cavity; the medial surface of the membrane is thus convex, and the point of greatest convexity is named the *umbo*.

Structure.—The tympanic membrane is composed of three strata: a lateral (cutaneous), an intermediate (fibrous), and a medial (mucous). The *cutaneous stratum* is derived from the skin which lines the external acoustic meatus, and consists of stratified epithelium. The *fibrous stratum* consists of two layers: a radiate stratum, the fibres of which diverge from the manubrium of the malleus, and a deeper circular stratum, the fibres of which are plentiful around the circumference but sparse and scattered near the centre of the membrane. Branched or dendritic fibres (Grüber) are also present, especially in the posterior half of the membrane. The *mucous stratum* is part of the mucous membrane of the tympanic cavity; it is thickest towards the upper part of the membrane, and is covered by a single layer of flattened cells. In the *pars flaccida* of the membrana tympani the fibrous stratum is replaced by loose connective tissue.

Vessels and Nerves.—The arteries of the tympanic membrane are derived from the deep auricular branch of the internal maxillary artery, which ramifies beneath the cutaneous stratum; and from the stylomastoid branch of the posterior auricular artery, and tympanic branch of the internal maxillary artery, which are distributed to the mucous surface. The superficial veins open into the external jugular vein; those on the deep surface drain partly into the transverse sinus and veins of the dura mater, and partly into a plexus of veins on the auditory tube. The membrane receives its nerve supply from the auriculotemporal branch of the mandibular nerve, the auricular branch of the vagus nerve, and the tympanic branch of the glossopharyngeal nerve.

The labyrinthic or medial wall (fig. 907) of the tympanic cavity is formed by the lateral wall of the internal ear. It presents for examination the fenestra vestibuli, the fenestra cochleæ, the promontory, and the prominence of the facial canal.

The *fenestra vestibuli* (fenestra ovalis) is a reniform opening, situated above and behind the promontory, and leading from the tympanic cavity into the vestibule of the internal ear; its long diameter is horizontal, and its convex border is upwards. In the recent state it is occupied by the base of the stapes, the circumference of which is fixed to the margin of the fenestra by the ligamentum annulare basos stapodis.

The *fenestra cochleæ* (fenestra rotunda) is situated below and a little behind the fenestra vestibuli, from which it is separated by the promontory. It is placed at the bottom of a funnel-shaped depression and, in the macerated bone, leads into the scala tympani of the cochlea; in the recent state it is closed by the secondary tympanic membrane, which is somewhat concave towards the tympanic cavity, and convex towards the cochlea, the membrane being bent so that its posterosuperior third forms an angle with its antero-inferior two-thirds. This membrane consists of three layers: an external, derived from the mucous lining of the tympanic cavity; an internal, from the lining membrane of the cochlea; and an intermediate, or fibrous layer.

The *promontory* is a rounded prominence, formed by the projection outwards of the first turn of the cochlea; it is placed between the fenestra vestibuli and fenestra cochleæ, and its surface is furrowed by small grooves which lodge the nerves of the tympanic plexus. A minute spicule of bone frequently connects the promontory to the pyramidal eminence.

The *prominence of the facial canal* indicates the position of the upper part of the bony canal (aqueductus Fallopii), in which the facial nerve is contained; this canal traverses the labyrinthic wall of the tympanic cavity above the fenestra vestibuli, and then curves downwards along the mastoid wall.

The *mastoid or posterior wall* of the tympanic cavity is wider above than below, and presents for examination the entrance to the tympanic antrum, the pyramidal eminence, and the fossa incudis.

The *entrance to the antrum* is a large irregular aperture, which leads backwards from the epitympanic recess into an air-space, named the *tympanic or mastoid antrum* (p. 206). The antrum communicates behind and below with

the *mastoid air-cells*, which vary considerably in number, size, and form; the antrum and mastoid air-cells are lined by mucous membrane, continuous with that lining the tympanic cavity. On the medial wall of the entrance to the antrum is a rounded eminence, situated above and behind the prominence of the facial canal; it corresponds with the position of the ampullated ends of the superior and lateral semicircular canals.

The *pyramidal eminence* is situated immediately behind the fenestra vestibuli, and in front of the vertical portion of the facial canal; it is hollow, and contains the Stapedius muscle; its summit projects forwards towards the fenestra vestibuli, and is pierced by a small aperture which transmits the tendon of the muscle. The cavity in the pyramidal eminence is prolonged downwards

FIG. 907.—A coronal section of the right temporal bone

and backwards in front of the facial canal, and communicates with it by a minute aperture which transmits a twig from the facial nerve to the Stapedius muscle.

The *fossa incudis* is a small depression in the lower and posterior part of the epitympanic recess; it lodges the short crus of the incus, which is fixed to the fossa by ligamentous fibres.

The *carotid* or *anterior wall* of the tympanic cavity is narrowed in its vertical diameter by the descent of the tegmen tympani; it is separated from the carotid canal by a thin plate of bone perforated by the tympanic branch of the internal carotid artery, and by the caroticotympanic nerves. At the upper part of the anterior wall are the orifice of the semicanal for the Tensor tympani muscle, and the tympanic orifice of the auditory tube, separated from each other by a thin horizontal plate of bone, the septum canalis musculotubarii. These canals run from the tympanic cavity forwards and downwards to the angle of union between the squama and the petrous portion of the temporal bone.

The *semicanal for the Tensor tympani* is the higher and the smaller of the two; it is cylindrical and lies beneath the tegmen tympani. It extends on to the labyrinthine wall of the tympanic cavity, and ends immediately above the fenestra vestibuli.

The *septum canalis musculotubarii* (processus cochleariformis) passes backwards below this semicanal, forming its lateral wall and floor; it expands above the anterior end of the fenestra vestibuli, and terminates there by curving laterally so as to form a pulley over which the tendon of the muscle passes.

The **auditory tube** (Eustachian tube) is the channel through which the tympanic cavity communicates with the nasal part of the pharynx. Its length is about 36 mm., and its direction is downwards, forwards, and medial-wards, forming an angle of about 45° with the sagittal plane and one of about 30° with the horizontal plane. It is formed partly of bone, partly of cartilage and fibrous tissue (fig. 903).

The *osseous portion* is about 12 mm. long. It begins in the carotid wall of the tympanic cavity, below the septum canalis musculotubarii, and, gradually narrowing, ends at the angle of junction of the squama and the petrous portion of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The *cartilaginous portion*, about 24 mm. long, is formed of a triangular plate of elastic fibrocartilage, the greater part of which is situated in the medial wall of the tube. The apex of the fibrocartilage is attached by fibrous tissue to the circumference of the medial end of the osseous portion of the tube, while its base lies directly under the mucous membrane of the lateral wall of the nasal part of the pharynx, where it forms an elevation, the *torus tubarius* or *cushion*, behind the pharyngeal orifice of the tube. The upper edge of the cartilage is bent laterally so as to present on transverse section the appearance of a hook; a groove or furrow is thus produced, which is open below and laterally, and this part of the canal is completed by fibrous membrane. The cartilage lies in a groove between the petrous part of the temporal and the great wing of the sphenoid; this groove ends opposite the middle of the medial pterygoid lamina. The cartilaginous and bony portions of the tube are not in the same plane, the former inclining downwards a little more than the latter. The diameter of the tube is not uniform throughout, being greatest at the pharyngeal orifice, least at the junction of the bony and cartilaginous portions, and again increased towards the tympanic cavity; the narrowest part of the tube is termed the *isthmus*. The position and relations of the pharyngeal orifice are described with the nasal part of the pharynx (p. 1076). The mucous membrane of the tube is continuous in front with that of the nasal part of the pharynx, and behind with that of the tympanic cavity; it is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of adenoid tissue, named by Gerlach the *tube-tonsil*. The tube is opened during deglutition by the Salpingopharyngeus and Dilator tubæ. The latter arises from the lateral lamina of the cartilage and from the membranous part of the tube, and blends below with the Tensor veli palatini. H. Blakeway* is of opinion that contraction of the Tensor veli palatini is more likely to produce closure than opening of the tube.

In the new-born child the auditory tube is about half as long as that of the adult. Its direction is more horizontal and its osseous portion is relatively shorter. Its pharyngeal orifice is a narrow slit which is on a level with the palate, and is devoid of a torus tubarius.

Vessels and Nerves.—The *arteries* of the auditory tube are derived from the ascending pharyngeal branch of the external carotid artery and from two branches of the internal maxillary artery, viz.:—the middle meningeal artery and the artery of the pterygoid canal. The *veins* open into the pterygoid venous plexus. The *nerves* of the tube spring from the pharyngeal plexus and from the pharyngeal branch of the sphenopalatine ganglion.

AUDITORY OSSICLES

The tympanic cavity contains a chain of three-movable ossicles, the *malleus*, *incus*, and *stapes*. The malleus is attached to the tympanic membrane, the stapes to the circumference of the fenestra vestibuli, while the incus is placed between the malleus and stapes and connected to them by delicate articulations.

* *Journal of Anatomy and Physiology*, vol. xlviii.

THE AUDITORY OSSICLES

The **malleus** (fig. 908), so named from its fancied resemblance to a hammer, is from 8 to 9 mm. long, and is the largest of the auditory ossicles. It consists of a head, neck, and three processes, viz. the manubrium, the anterior and lateral processes.

The **head**, the large upper end of the bone, is situated within the epitympanic recess; it is ovoid in shape, and articulates posteriorly with the incus, being

FIG. 908.—The left malleus. A. From behind. B. From within.

free in the rest of its extent. The facet for articulation with the incus is constricted near the middle, and consists of an upper larger, and lower smaller part, situated nearly at right angles to one another. Opposite the constriction the lower margin of the facet projects in the form of a process, the *cog-tooth* or *spur* of the malleus.

The **neck** is the contracted part just beneath the head; below the neck is an enlargement to which the various processes are attached.

The **manubrium mallei** is connected by its lateral margin with the tympanic membrane. It is directed downwards, medialwards, and backwards; it decreases in size towards its free end, which is curved slightly forwards and flattened transversely. Near the upper end of its medial surface is a slight projection, into which the tendon of the Tensor tympani is inserted.

The **anterior process** (*processus gracilis*) is a delicate spicule, directed forwards from the enlargement below the neck; it is connected to the petrotympanic fissure by ligamentous fibres. In the foetus this is the longest process of the malleus, and is continuous in front with the cartilage of Meckel (p. 77).

The **lateral process** (*processus brevis*) is a slight conical projection, which springs from the root of the manubrium; it is directed laterally, and is attached to the upper part of the tympanic membrane and, by means of the anterior and posterior malleolar folds, to the extremities of the notch of Rivinus.

The **incus** (fig. 909) has received its name from its supposed resemblance to an anvil, but its shape is more like that of a premolar tooth, with two widely separated roots. It consists of a body and two crura.

The **body** is somewhat cubical but compressed transversely. On its anterior surface is a saddle-shaped facet, for articulation with the head of the malleus.

The two crura diverge from one another nearly at right angles.

The **short crus**, somewhat conical in shape, projects backwards, and is attached by ligamentous fibres to the fossa incudis, in the lower and posterior part of the epitympanic recess.

The **long crus**, rather more than half the length of the manubrium mallei, descends nearly vertically behind and parallel to that process; its lower end bends medialwards, and terminates in a rounded projection, the **lenticular**

FIG. 909.—The left incus. A. From within. B. From the front.

process, the inner surface of which is covered with cartilage, and articulates with the head of the stapes.

The **stapes** (fig. 910), so called from its resemblance to a stirrup, consists of a head, neck, two crura, and a base.

On the *head*, which is directed lateralwards, is a depression for articulation with the lenticular process of the incus.

FIG. 910.—A. The left stapes. B. Medial surface of the head of the stapes.

On the *neck* or constricted part succeeding the head, the tendon of the Stapedius muscle is inserted.

The *crura* diverge from the neck and are connected at their ends by a flattened oval plate, the *base*, which forms the footplate of the stirrup and is fixed to the margin of the fenestra vestibuli by a ring of ligamentous fibres. The anterior crus is shorter and less curved than the posterior.

Articulations of the auditory ossicles.—The incudomalleolar joint is a saddle-shaped diarthrosis; it is surrounded by an articular capsule, and the joint-cavity is incompletely divided into two by a wedge-shaped articular disc or meniscus. The incudostapedial joint is an enarthrosis, surrounded by an articular capsule; some observers have described an articular disc or meniscus in this joint; others regard the joint as a syndesmosis.

Ligaments of the ossicles.—The ossicles are connected to the walls of the tympanic cavity by ligaments: three for the malleus, and one each for the incus and stapes.

The *anterior ligament of the malleus* is attached by one end to the neck of the malleus, just above the anterior process, and by the other to the anterior wall of the tympanic cavity, close to the petrotympanic fissure, some of its fibres being prolonged through the fissure, to reach the spina angularis of the sphenoid.

The *lateral ligament of the malleus* is a triangular band passing from the posterior part of the notch of Rivinus to the head of the malleus. Helmholtz described the anterior ligament and the posterior part of the lateral ligament as forming together the '*axis ligament*' around which the malleus rotates.

The *superior ligament of the malleus* connects the head of the malleus to the roof of the epitympanic recess.

The *posterior ligament of the incus* connects the end of the short crus of the incus to the fossa incudis.

A *superior ligament of the incus* has been described, but it is little more than a fold of mucous membrane.

The vestibular surface and the circumference of the base of the stapes are covered with hyaline cartilage; that encircling the base is attached to the margin of the fenestra vestibuli by a ring of elastic fibres, the *ligamentum annulare baseos stapedis*.

Movements of the auditory ossicles.—The manubrium mallei follows all the movements of the tympanic membrane, while the malleus and incus rotate together around an axis which runs through the short process of the incus and the anterior ligament of the malleus. When the tympanic membrane and manubrium mallei are propelled inwards the long process of the incus also moves in the same direction and pushes the base of the stapes towards the labyrinth. This motion is communicated to the fluid (perilymph) contained within the labyrinth and the movement of the perilymph causes an outward bulging of the secondary tympanic membrane which closes the fenestra cochleæ. The conditions are reversed when the tympanic membrane moves in a lateral direction, but if this movement of the membrane be exaggerated the incus does not follow the full outward excursion of the malleus, but merely glides on this bone at the incudomalleolar joint, and thus the danger of pulling the foot of the stapes out of the fenestra vestibuli is prevented. When the manubrium mallei is carried inwards the cog-tooth or spur on the lower margin of the head of the malleus locks the incudomalleolar joint, and this necessitates an inward movement of the long process of the incus; the joint is unlocked when the manubrium mallei is carried outwards.

The **muscles of the tympanic cavity** are the Tensor tympani and Stapedius.

The *Tensor tympani*, the larger, is contained in the bony canal above the osseous portion of the auditory tube, from which it is separated by the septum

canalis musculotubarii. It arises from the cartilaginous portion of the auditory tube and the adjoining part of the great wing of the sphenoid, as well as from the osseous canal in which it is contained. Passing backwards through the canal, it ends in a slender tendon which enters the tympanic cavity, makes a sharp bend round the pulley-like posterior end of the septum, and is inserted into the manubrium mallei, near its root. It is supplied by a branch of the mandibular nerve through the otic ganglion.

The *Stapedius* arises from the wall of a conical cavity hollowed out of the interior of the pyramidal eminence; its tendon emerges from the orifice at the apex of the eminence, and, passing forwards, is inserted into the posterior surface of the neck of the stapes. It is supplied by a branch of the facial nerve.

Actions.—The Tensor tympani draws the manubrium mallei and the tympanic membrane medialwards, and thus increases the tension of the membrane. The Stapedius pulls back the head of the stapes, and thus causes the base of the bone to rotate on a vertical axis drawn through its own centre; the posterior part of the base is pressed inwards towards the vestibule, while the anterior part is withdrawn from it. By the action of the muscle the tension of the fluid within the internal ear is probably increased.

The mucous membrane of the tympanic cavity is continuous with that of the pharynx, through the auditory tube. It invests the auditory ossicles, and the muscles and nerves contained in the tympanic cavity; forms the medial layer of the tympanic membrane, and the lateral layer of the secondary tympanic membrane, and lines the tympanic antrum and mastoid cells. It forms several vascular folds, which extend from the walls of the tympanic cavity to the ossicles; of these, one descends from the roof of the cavity to the head of the malleus and upper margin of the body of the incus, a second invests the Stapedius muscle; other folds invest the chorda tympani nerve and the Tensor tympani muscle. These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honeycombed appearance. One of these pouches, the *pouch of Prussak*, is well marked and lies between the neck of the malleus and the membrana flaccida. Two other recesses may be mentioned: they are formed by the mucous membrane which envelops the chorda tympani nerve, and are situated, one in front of, and the other behind, the manubrium of the malleus; they are named the *anterior and posterior recesses of Tröltsch*. In the tympanic cavity the mucous membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but over the pyramidal eminence, ossicles, and tympanic membrane it possesses a flattened non-ciliated epithelium. In the tympanic antrum and mastoid cells its epithelium is also non-ciliated.

Vessels and Nerves.—The arteries are six in number. Two of them are larger than the others, viz. the tympanic branch of the internal maxillary artery, which supplies the tympanic membrane; and the stylo-mastoid branch of the posterior auricular artery, which is distributed to the posterior part of the tympanic cavity and mastoid cells. The smaller arteries are—the petrosal branch of the middle meningeal artery, which enters through the hiatus of the facial canal; a branch from the ascending pharyngeal artery, and another from the artery of the pterygoid canal, which accompany the auditory tube; and the tympanic branch from the internal carotid artery, given off in the carotid canal and perforating the thin anterior wall of the tympanic cavity. The veins terminate in the pterygoid venous plexus and in the superior petrosal sinus. The nerves constitute the tympanic plexus, which ramifies upon the surface of the promontory. The plexus is formed by (1) the tympanic branch of the glossopharyngeal nerve; (2) the carotico-tympanic nerves; (3) the smaller superficial petrosal nerve; and (4) a branch which joins the greater superficial petrosal nerve.

The tympanic branch of the glossopharyngeal (Jacobson's nerve) enters the tympanic cavity by the inferior tympanic canaliculus, and divides into branches which ramify on the promontory and enter into the formation of the tympanic plexus. The superior and inferior carotico-tympanic nerves, from the carotid plexus of the sympathetic, pass through the wall of the carotid canal, and join the filaments of the tympanic branch of the glossopharyngeal. The branch to the greater superficial petrosal passes through an opening on the labyrinthine wall, in front of the fenestra vestibuli. The smaller superficial petrosal nerve, from the otic ganglion, passes backwards through a foramen in the middle fossa of the base of the skull (sometimes through the foramen ovale), and enters the anterior surface of the petrous part of the temporal bone through a small aperture, situated laterally to the hiatus of the facial canal; it courses downwards through the bone, past the genicular ganglion of the facial nerve, receiving a connecting filament from it, and enters

the tympanic cavity, where it communicates with the tympanic branch of the glossopharyngeal, and assists in forming the tympanic plexus.

The *branches of distribution* of the tympanic plexus are supplied to the mucous membrane of the tympanic cavity; a branch passes to the fenestra vestibuli, another to the fenestra cochleæ, and a third to the auditory tube. The smaller superficial petrosal nerve may be looked upon as the continuation of the tympanic branch of the glossopharyngeal nerve through the tympanic plexus to the otic ganglion.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the mandibular nerve through the otic ganglion, and the Stapedius by a branch from the facial nerve.

The *chorda tympani nerve* crosses the tympanic cavity. It is given off from the sensory part of the facial nerve, about 6 mm. before that nerve emerges from the stylo-mastoid foramen. It runs upwards and forwards in a canal, and enters the tympanic cavity through the *iter chordæ posterius*, and becomes invested with mucous membrane. It traverses the tympanic cavity, crossing medially to the tympanic membrane and over the upper part of the manubrium of the malleus to the carotid wall, where it emerges through the *iter chordæ anterior*, or canal of Huguier.

Applied Anatomy.—Fractures of the middle fossa of the base of the skull almost invariably involve the tympanic roof, and are accompanied by a rupture of the tympanic membrane or fracture through the roof of the bony meatus. They are associated with profuse continued bleeding from the ear, and, if the dura has also been lacerated, with discharge of copious amounts of cerebrospinal fluid. Here the avoidance of infection from the outside is of the utmost importance, as should it occur septic meningitis must inevitably follow with a fatal issue.

The tympanic cavity is very frequently the seat of disease, both suppurative and non-suppurative, and in practically every case the inflammation spreads upwards from the nose or throat along the auditory tube. Acute inflammatory troubles spreading up to the tympanic cavity are usually associated with so much inflammatory swelling of the mucous membrane of the auditory tube as to occlude it, and thus the products of inflammation are pent up in the tympanic cavity and directly involve the tympanic antrum. Under such circumstances the only means of escape for the products is by rupture of the tympanic membrane which usually occurs spontaneously and is followed by a free discharge of pus, with relief to the acute pain which exists in this condition. Should the swelling of the walls of the auditory tube then subside, the normal drainage of the cavity will be established and the perforation in the drum will heal, but if not—as is often the case because the opening of the tube may be occluded by adenoid growths in the nasopharynx or other cause—the pus will continue to accumulate in the middle ear and will overflow through the perforation as a chronic otorrhœa. In the course of time the disease spreads beyond the mucous membrane to the walls of the tympanic cavity, to the ossicles, or to the mastoid process, and when this has occurred the condition is incurable except by the removal of the carious bone. Further, severe intracranial complications are at this time often produced owing to purulent material being retained; thus an abscess may form between the bone and dura mater, (a) about the roof of the tympanic cavity, and immediately beneath the dura covering the temporal lobe, or (b) between the deep aspect of the mastoid process and the sigmoid bend of the transverse sinus, possibly extending widely and surrounding the sinus. In this latter type of case thrombosis of the transverse sinus readily occurs, and the clot being also infected tends to disintegrate and be carried into the general circulation, particles becoming lodged in the capillaries of the lungs and setting up abscesses therein. Pyæmia from transverse sinus thrombosis is more common than from any other focus of origin. In addition, bone disease of the tympanic cavity or antrum may be associated with severe and fatal septic meningitis, or with the formation of abscess in the brain, the most common sites being the temporal lobe and the hemisphere of the cerebellum.

Less serious, but more common, is the formation of a subperiosteal mastoid abscess with great swelling behind the ear, and protrusion outwards of the auricle; such a condition demands an early incision through all the structures, including the periosteum, over the whole length of the mastoid process, and then it will frequently be found that the underlying bone is carious or that a track leads through the bone into the tympanic antrum. In such conditions extensive operations for the removal of bone are often required. In many cases of chronic bone disease in the tympanic cavity, the facial nerve becomes exposed as it lies in its canal, and an inflammatory process is set up in the nerve, leading to facial paralysis of the infranuclear type (p. 871). In other cases localised areas of bone disease, most often in the region of the epitympanic recess, form the points from which aural polypi grow, and the ear polypus, like the nasal polypus, must be considered to have originated in a spot of carious bone, the removal of which is necessary if a cure is to be established.

Of the non-suppurative conditions which affect the middle ear, chronic catarrh, leading to sclerosis of the whole of the tympanic contents, is again due to spread of inflammation from some nasal or pharyngeal condition. The progress is very slow, but leads to ever-increasing deafness—this deafness in the first instance is in no way connected with any defect in the acoustic nerve, and this can be shown by the fact that the hearing by bone conduction over the mastoid process remains normal. In chronic non-suppurative otitis

media; treatment must be especially directed towards placing the nose and pharynx in a healthy condition; when this has been accomplished, the aural condition often improves of itself; if not, improvement may be induced by forcing air up the auditory tube by means of the Politzer bag, or directly into the office of the tube by means of a catheter.

INTERNAL EAR, OR LABYRINTH

The internal ear is the essential part of the organ of hearing, receiving the ultimate distribution of the auditory nerve. It is called the labyrinth, from the complexity of its shape, and consists of two parts: the *osseous labyrinth*, a series of cavities within the petrous part of the temporal bone, and the *membranous labyrinth*, a series of communicating membranous sacs and ducts, contained within the bony cavities.

THE OSSEOUS LABYRINTH (figs. 911, 912)

The *osseous labyrinth* consists of three parts: the *vestibule*, *semicircular canals*, and *cochlea*. These are cavities hollowed out of the substance of the

FIG. 911.—The right osseous labyrinth. Lateral view.

bone, and lined by periosteum; they contain a clear fluid, the perilymph, in which the membranous labyrinth is placed.

The *vestibule* is the central part of the osseous labyrinth, and is situated medially to the tympanic cavity, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoid in shape, but flattened transversely; it measures about 5 mm. from before backwards, the same from above downwards, and about 3 mm. across. In its *lateral or tympanic wall* is the *fenestra vestibuli*, closed in the recent state by the base of the stapes and its annular ligament. At the front part of the *medial wall* is a small circular depression, the *recessus sphaericus*, which is perforated at its anterior and inferior part by several minute holes (*macula cribrosa media*) for the passage of filaments of the acoustic nerve to the sacculus. Behind this recess is an oblique ridge, the *crista vestibuli*, the anterior end of which is named the *pyramid of the vestibule*; this ridge divides below to enclose a small depression, the *fossa cochlearis*, which is perforated by a number of holes for the passage of filaments of the acoustic nerve to the vestibular end of the ductus cochlearis. At the hinder part of the medial wall is the orifice of the *aqueductus vestibuli*. This aqueduct extends to the posterior surface of the petrous portion of the temporal bone; it transmits a small vein, and contains a tubular prolongation of the membranous labyrinth, the *ductus endolymphaticus*. On the *upper wall or roof* is a transversely elliptical depression, the *recessus ellipticus*, separated anteriorly from the recessus sphaericus by the *crista vestibuli* already mentioned. The pyramid and adjoining part of the recessus ellipticus are perforated by a number of

holes (*macula cribrosa superior*); the holes in the pyramid transmit the nerves to the utricle, and those in the recessus ellipticus the nerves to the ampullæ of the superior and lateral semicircular ducts. Behind are the five orifices of the semicircular canals. In front is an elliptical opening which communicates with the scala vestibuli of the cochlea.

The bony semicircular canals are three in number, superior, posterior, and lateral, and are situated above and behind the vestibule. They are compressed from side to side, and each describes the greater part of a circle. They are unequal in length, but each measures about 0.8 mm. in diameter and presents a dilatation at one end, called the *ampulla*, the diameter of which is more than twice that of the canal. They open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The *superior semicircular canal*, 15 to 20 mm. in length, is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a circle. Its lateral extremity is ampullated,

FIG. 912.—The interior of the right osseous labyrinth.

and opens into the upper part of the vestibule; the opposite end joins with the upper end of the posterior canal to form the *crus commune*, which opens into the upper and medial part of the vestibule.

The *posterior semicircular canal*, also vertical, is directed backwards, nearly parallel to the posterior surface of the petrous bone; it is from 18 mm. to 22 mm. long; its lower or ampullated end opens into the lower and posterior part of the vestibule, where are seen several small holes (*macula cribrosa inferior*) for the transmission of the nerves to this ampulla. Its upper end opens into the *crus commune* already mentioned.

The *lateral or horizontal canal* is from 12 mm. to 15 mm. long, and its arch is directed horizontally backwards and lateralwards. The ampullated end of this canal corresponds to the upper and lateral angle of the vestibule, just above the fenestra vestibuli, where it opens close to the ampullated end of the superior canal; its opposite end opens at the upper and posterior part of the vestibule, below the opening of the *crus commune*.

The lateral semicircular canal of one ear is very nearly in the same plane as that of the other; while the superior canal of one ear is nearly parallel to the posterior canal of the other; thus each semicircular canal stands at right angles to the other two.

The *cochlea* (figs. 912, 913) bears a resemblance to the shell of the common snail; it forms the anterior part of the labyrinth, is conical in form, and placed in front of the vestibule; it measures about 5 mm. from base to apex, and its breadth across the base is about 9 mm. Its apex (cupula) is directed

forwards and lateralwards, with a slight inclination downwards, towards the upper and front part of the labyrinthic wall of the tympanic cavity; its base corresponds with the bottom of the internal acoustic meatus, and is perforated by numerous apertures for the passage of the cochlear nerve. The cochlea * consists of a conical-shaped central axis, the *modiolus*; of a canal, wound spirally around the central axis for two turns and three-quarters; and of a delicate lamina, the *osseous spiral lamina*, which projects from the modiolus into the canal, and partially subdivides it. In the recent state the subdivision of the canal is completed by the *basilar membrane* which stretches from the free border of the bony lamina to the outer wall of the bony cochlea; the two passages into which the cochlear canal is thus divided communicate with each other at the apex of the modiolus by a small opening, named the *helicotrema*.

FIG. 913.—The cochlea and vestibule, viewed from above. (Testut.)

All the hard parts which form the roof of the internal ear have been removed with the saw. A. Cochlea. B. Vestibule. C. Internal acoustic meatus. D. Tympanic cavity. 1. Section of promontory. 2. Non-amputated end of lateral semicircular canal. 9. Scala tympani of the cochlea. 10. Scala vestibuli. 11. Cupula. 12. Lamina spiralis ossea, with 12', its vestibular origin; 12'', its external border. 13. Helicotrema. 14. Bony wall of cochlea.

The *modiolus* is the conical central axis or pillar of the cochlea. Its base is broad, and appears at the bottom of the internal acoustic meatus, where it corresponds with the tractus spiralis foraminosus which is perforated by numerous orifices, for the transmission of the branches of the cochlear nerve; the nerves for the first turn and a half of the cochlea pass through the foramina of the tractus spiralis foraminosus; those for the apical turn, through the foramen centrale. The canals of the tractus spiralis foraminosus pass up through the modiolus and successively bend outwards to reach the attached margin of the lamina spiralis ossea. Here they become enlarged, and by their apposition form the *spiral canal of the modiolus*, which follows the course of the attached margin of the osseous spiral lamina and lodges the spiral ganglion (ganglion of Corti). The foramen centrale is continued into a canal which runs up the middle of the modiolus to its apex. The modiolus diminishes rapidly in size in the second and succeeding coil.

The bony canal of the cochlea takes two turns and three-quarters round the modiolus. It is about 30 mm. in length, and diminishes gradually in diameter from the base to the summit, where it terminates in the *cupula*, which forms the

* In the description which follows the cochlea is supposed to be resting on its base.

apex of the cochlea. The beginning of this canal is about 3 mm. in diameter ; it diverges from the modiolus towards the tympanic cavity and vestibule, and presents three openings. One, the *fenestra cochleæ*, communicates with the tympanic cavity and in the recent state is closed by the *secondary tympanic membrane* ; another, of an elliptical form, opens into the vestibule. The third is the aperture of the aqueductus cochleæ, leading to a minute funnel-shaped canal which opens on the inferior surface of the petrous part of the temporal bone and transmits a small vein, and also forms a communication between the subarachnoid cavity and the scala tympani.

The *osseous spiral lamina* is a bony shelf or ledge which winds round and projects from the modiolus into the interior of the canal, like the thread of a screw. It reaches about halfway across the canal, and incompletely divides it into two passages or *scalæ* : an upper, named the *scala vestibuli*, and a lower, the *scala tympani*. Near the summit of the cochlea the osseous spiral lamina ends in a hook-shaped process, the *hamulus laminae spiralis* ; this assists in forming the boundary of a small opening, the *helicotrema*, through which the two *scalæ* communicate with each other. From the spiral canal of the modiolus numerous canals pass outwards through the osseous spiral lamina as far as its free edge and transmit branches of the cochlear nerve. In the lower part of the first turn of the cochlea a *secondary spiral lamina* projects inwards from the outer wall of the bony tube ; it does not, however, reach the osseous spiral lamina, so that if the laminae be viewed from the vestibule a narrow fissure, the *fissura vestibuli*, is seen between them.

The *ossecus labyrinth* is lined by a thin fibroserous membrane which is closely adherent to the bone ; the free surface of the membrane is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the *perilymph*. A tubular process of this membrane is prolonged through the aqueductus vestibuli to the inner surface of the dura mater.

THE MEMBRANOUS LABYRINTH (figs. 914, 915, 916)

The *membranous labyrinth* is lodged within the bony labyrinth ; it is filled with fluid named *endolymph*, and in its walls the branches of the acoustic

FIG. 914.—The membranous labyrinth. (Schematic.) (Enlarged.)

nerve are distributed. It consists of : (a) two small sacs, the *utricle* and *sacculus*, lodged in the vestibule ; (b) three *semicircular canals*, enclosed within the *semicircular canals* ; and (c) the *ductus cochlearis*, contained within the bony cochlea. The various parts of the membranous labyrinth communicate with one another ; the semicircular ducts open into the utricle, the utricle into the saccule through the ductus endolymphaticus, and the saccule into the ductus cochlearis through the *canalis reuniens of Hansen*.

The membranous labyrinth is fixed at certain points to the wall of the bony labyrinth, but is separated from the greater part of the bony labyrinth by a perilymphatic space which contains a fluid named *perilymph*. The perilymphatic space of the vestibule communicates behind with that of the semicircular canals, and opens anteriorly into the scala vestibuli of the cochlea, which in turn opens into the scala tympani through the helicotrema, at the apex of the cochlea. The scala tympani is separated from the tympanic cavity by the secondary tympanic membrane, but is continuous with the subarachnoid cavity through the aqueductus cochleæ.

The utricle, the larger of the two vestibular sacs, is irregularly oblong in shape, compressed transversely, and occupies the upper and posterior part of the vestibule, lying in contact with the recessus ellipticus and the part below it. That portion which is lodged in the recessus ellipticus forms a sort of pouch

FIG. 915.—The right membranous labyrinth of a fifth-month human embryo. $\times 10$. Anterolateral aspect. (G. Retzius.)

or cul-de-sac; the floor and anterior wall of this are thickened, and form the *macula acustica utricle*, which receives the utricular filaments of the acoustic nerve. The cavity of the utricle communicates behind with the semicircular ducts by five orifices. From its anteromedial part a fine canal, the *ductus utriculosaccularis*, is given off, and opens into the ductus endolymphaticus.

The *sacculus* is globular in form, and lies in the recessus sphaericus near the opening of the scala vestibuli of the cochlea. Its anterior part exhibits an oval thickening, the *macula acustica saccule* (fig. 918), to which are distributed the saccular filaments of the acoustic nerve. Its cavity does not directly communicate with that of the utricle. From its posterior part a canal, the *ductus endolymphaticus*, is given off; this duct is joined by the ductus utriculosaccularis, and then passes along the aqueductus vestibuli and ends in a blind pouch (*sacculus endolymphaticus*), under the dura mater on the posterior surface of the petrous portion of the temporal bone. From the lower part of the sacculus a short tube, the *canalis reuniens* of Hensen, passes downwards and opens into the ductus cochlearis near its vestibular extremity (fig. 914).

The *semicircular ducts* (figs. 915, 916) are about one-fourth of the diameter of the osseous semicircular canals, but in number, shape, and general form they are precisely similar, and each presents at one end an ampulla.

They open by five orifices into the utricle, one opening being common to the medial end of the superior and the upper end of the posterior duct. In each of the ampullæ the wall is thickened, and projects into the cavity as a transverse elevation shaped somewhat like the figure 8, and named the *septum transversum*; the most prominent part of this septum is termed the *crista ampullaris* in which the nerves end.

The utricle, saccule, and semicircular ducts are held in position by numerous fibrous bands which stretch across the perilymphatic space to the bony walls.

FIG. 916.—The right membranous labyrinth of a fifth-month human embryo. $\times 10$. Posteromedial aspect. (G. Retzius.)

Structure (fig. 917).—The walls of the utricle, saccule, and semicircular ducts consist of three layers. The *outer layer* is composed of ordinary fibrous tissue containing blood-vessels and some pigment-cells. The *middle layer*, thicker and more transparent, is named the *tunica propria*, and presents on its internal surface, especially in the semicircular ducts, numerous papilliform projections, which on the addition of acetic acid, exhibit an appearance of longitudinal fibrillation. The *inner layer* is formed of polygonal nucleated epithelial cells. In the maculæ of the utricle and saccule (fig. 918), and in the cristæ ampullares of the semicircular ducts, the middle coat is thickened and the epithelium is columnar, and consists of *supporting cells* and *hair-cells*. The supporting cells are fusiform, and their deep ends are attached to the membrana propria, while their free extremities are united to form a thin cuticle. The hair-cells are flask-shaped, and their deep, rounded ends do not reach the membrana propria, but lie between the supporting cells. The deep part of each hair-cell contains a large nucleus, while its more superficial part is granular and pigmented. The free end of the cell is surmounted by a long, tapering, hair-like filament, which projects into the cavity. The filaments of the vestibular nerve, having pierced the tunica propria, lose their medullary sheaths, and their axis-cylinders split up into fine fibrils which end between the hair-cells.

Two small rounded bodies termed *otoconia*, consisting of crystals of carbonate of lime, are suspended in the endolymph in contact with the free ends of the hairs projecting from the maculæ.

The *ductus cochlearis* or *scala media* consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall.

As already stated (p. 996) the osseous spiral lamina extends only part of the distance between the modiolus and the outer wall of the cochlea, while the *basilar membrane* stretches from the free edge of the lamina to the outer wall of the cochlea, and completes the roof of the *scala tympani*. A second

and more delicate membrane, the *vestibular membrane* (*Reissneri*) extends from the thickened periosteum covering the osseous spiral lamina to the outer wall of the cochlea, where it is attached at some little distance above the outer edge of the basilar membrane. A canal is thus shut off between the *scala tympani* below and the *scala vestibuli* above; this is the *ductus cochlearis* or *scala media* (figs. 919, 920). It is triangular on transverse section, its roof

FIG. 918.—A transverse section of the macula acustica sacculi. (Retzius.)

being formed by the vestibular membrane, its outer wall by the periosteum lining the bony canal, and its floor by the membrana basilaris and the outer part of the lamina spiralis ossea. Its extremities are closed; the upper, termed the *lagena*, is attached to the cupula cochleæ and partly bounds the helicotrema;

1000 ORGANS OF THE SENSES AND COMMON INTEGUMENT

the lower is lodged in the recessus cochlearis of the vestibule. Near the lower extremity the ductus cochlearis communicates with the sacculæ by the narrow, short *canalis reuniens* of Hensen (fig. 914). On the *membrana basilaris* is situated the spiral organ of Corti. The vestibular membrane is thin and

FIG. 919.—A diagrammatic longitudinal section of the cochlea.

homogeneous, and is covered on its upper and under surfaces by a layer of flattened epithelium. The periosteum forming the outer wall of the ductus cochlearis is greatly thickened and altered in character. It projects inwards inferiorly as a triangular prominence, the *crista basilaris*, to which the outer edge of the basilar membrane is fixed; immediately above this is a concavity,

FIG. 920.—A transverse section across the middle coil of the ductus cochlearis. (Retzius.)

the *sulcus spiralis externus*, above which the periosteum contains numerous blood-vessels, and is termed the *stria vascularis*.

The osseous spiral lamina consists of two plates of bone, and between these are the canals for the transmission of the filaments of the acoustic nerve. On the upper plate of that part of the lamina which is contained within the

ductus cochlearis the periosteum is thickened to form the *limbus laminae spiralis* (fig. 921); this ends externally in a concavity, the *sulcus spiralis internus*, which represents, on section, the form of the letter C; the upper part, formed by the overhanging edge of the limbus, is named the *vestibular lip*; the lower part, prolonged and tapering, is called the *tympanic lip*, and is perforated by numerous foramina for the passage of the branches of the cochlear nerve. The upper surface of the vestibular lip is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth on the free surface and margin of the lip, and were named by Huschke the *auditory teeth* (fig. 921). The limbus is covered by a layer of what appears to be squamous epithelium, but only the cells covering the teeth are flattened, those in the furrows being columnar, and

Part of the vestibular membrane.

occupying the intervals between the elevations. This layer of epithelium is continuous on the one hand with that lining the sulcus spiralis internus, and on the other with that covering the under surface of the vestibular membrane.

Basilar membrane.—The basilar membrane stretches from the tympanic lip of the osseous spiral lamina to the basilar crest. Its width increases from 0.21 mm. in the basal turn to 0.36 mm. in the apical turn of the cochlea. Its inner part is thin, and is named the *zona arcuata*; it supports the spiral organ of Corti; the outer part is thicker and striated, and is termed the *zona pectinata*. The under surface of the membrane is covered by a layer of vascular connective tissue; one of the vessels in this tissue is somewhat larger than the rest, and is named the *vas spirale*; it lies below Corti's tunnel.

The spiral organ of Corti (figs. 920, 922) is composed of a series of epithelial structures placed upon the inner part of the basilar membrane. The more central of these structures are two rows of rod-like bodies, the *inner and outer rods* or *pillars of Corti*. The bases of the rods are supported on the basilar membrane, those of the inner row at some distance from those of the outer; the two rows incline towards each other and, coming into contact above, enclose between them and the basilar membrane the *tunnel of Corti*, which is triangular in cross section. On the inner side of the inner rods is a single row of hair-cells, and on the outer side of the outer rods three or four rows of hair-cells, together with certain supporting cells.

of Hensen. The free ends of the outer hair-cells occupy a series of apertures in a net-like membrane, the reticular membrane, and the entire organ is covered by the tectorial membrane.

Rods of Corti.—Each of these consists of a base or foot-plate, an elongated part or body, and an upper end or head; the body of each rod is finely striated, but in the head there is an oval non-striated portion which stains deeply with carmine. Occupying the angles between the rods and the basilar membrane are nucleated cells which partly envelop the rods and extend on to the floor of Corti's tunnel; these may be looked upon as the undifferentiated parts of the cells from which the rods have been formed.

The *inner rods* number nearly 6000, and their bases rest on the basilar membrane close to the tympanic lip of the sulcus spiralis internus. The shaft or body of each is sinuously curved and forms an angle of about sixty degrees with the basilar membrane. The head resembles the proximal end of the ulna, and presents a deep concavity which accommodates a convexity on the head of the outer rod. The head-plate, or portion overhanging the concavity, overlaps the head-plate of the outer rod.

FIG. 922.—A transverse section through the spiral organ of Corti. Magnified. (G. Retzius.)

The *outer rods*, nearly 4000 in number, are longer and more obliquely set than the inner, forming with the basilar membrane an angle of about forty degrees. Their heads are convex internally: they fit into the concavities on the heads of the inner rods, and are continued outwards as thin flattened plates, termed *phalangeal processes*, which unite with the phalangeal processes of Deiters' cells to form the reticular membrane.

Hair-cells.—The hair-cells are short columnar cells; their free ends are on a level with the heads of Corti's rods, and each is surmounted by about twenty hair-like processes arranged in the form of a crescent with its concavity directed inwards. The deep ends of the cells reach about halfway along Corti's rods, and each contains a large nucleus; in contact with the deep ends of the hair-cells are the terminal filaments of the cochlear nerve. The *inner hair-cells*, about 3500 in number, are arranged in a single row on the medial side of the inner rods, and, their diameters being greater than those of the rods, each is supported by more than one rod. The free ends of the inner hair-cells are encircled by a cuticular membrane which is fixed to the heads of the inner rods. Adjoining the inner hair-cells are one or two rows of columnar supporting cells, which, in turn, are continuous with the cubical cells lining the sulcus spiralis internus. The *outer hair-cells* number about 12,000, and are nearly twice as long as the inner. In the basal coil of the cochlea they are arranged in three regular rows; in the apical coil, in four somewhat irregular rows.

Between the rows of the outer hair-cells are rows of supporting cells, called the *cells of Deiters*; their expanded bases are planted on the basilar membrane, while the opposite end of each presents a clubbed extremity or *phalangeal* process. Immediately to the outer side of Deiters' cells are five or six rows of columnar cells, the *supporting cells of Hensen*. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen's cells are termed the *cells of Claudius*. A space exists between the outer rods of Corti and the adjacent hair-cells; this is called the *space of Nuel*.

The *reticular lamina* (fig. 923) is a delicate framework perforated by circular holes which are occupied by the free ends of the outer hair-cells. It extends from the heads of the outer rods of Corti to the external row of the outer hair-cells, and is formed by several rows of minute fiddle-shaped cuticular structures,

FIG. 923.—The lamina reticularis and subjacent structures. (Schematic.) (Testut.)

called *phalanges*, between which are circular apertures containing the free ends of the hair-cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters' cells.

The *teclorial membrane* overlies the sulcus spiralis internus and the spiral organ of Corti. It is wider and thicker in the apical than in the basal part of the cochlea. Its inner part is thin and is attached to the vestibular lip of the limbus laminae spiralis, the attachment reaching as far as the vestibular membrane. The outer part is thick and padlike, the thickness being greatest over, or slightly to the inner side of the upper ends of Corti's rods. Retzius described the outer edge as being attached to the outer row of Deiters' cells while others maintain that it forms a ragged or frayed margin. Hardesty,* who has examined the membrane in the pig, states that this edge is free and bluntly rounded, but finely and irregularly scalloped. On the under surface of the membrane, opposite the interval between the inner and outer rows of hair-cells is a band, named *Hensen's stripe*.

Hardesty has shown that the membrane "consists of multitudes of delicate fibrils embedded in a transparent matrix of a soft, collagenous, semi-solid character with marked

* *American Journal of Anatomy*, vol. viii.

adhesiveness.* The prevailing course of the fibres is obliquely transverse, slanting from the vestibular lip towards the apex of the cochlea. The fibres pass in curves from the vestibular lip and upper surface of the membrane to its under surface, where by their interlacement they produce the appearance known as Hensen's stripe. He also describes a thin, exceedingly delicate *accessory tectorial membrane*, lying along the under surface of the outer zone of the main membrane, and lightly attached to the latter by its outer edge.

The **acoustic nerve**, or nerve of hearing, divides near the bottom of the internal acoustic meatus into an anterior or cochlear, and a posterior or vestibular portion. The deep connexions of these nerves are described on pp. 872 to 874.

The *vestibular nerve* supplies the utricle, the saccule, and the ampullæ of the semicircular ducts. On the trunk of the nerve, within the internal acoustic meatus, is the *vestibular ganglion* (ganglion of Scarpa), from the nerve-cells of which the fibres of the nerve take origin. On the distal side of the ganglion the nerve splits into a superior, an inferior, and a posterior branch.* The filaments of the *superior branch* are transmitted through the foramina in the area vestibularis superior, and end in the macula of the utricle and in the cristæ of the ampullæ of the superior and lateral semicircular ducts; those of the *inferior branch* traverse the foramina in the area vestibularis inferior, and end in the macula of the saccule. The *posterior branch* runs through the foramen singulare at the postero-inferior part of the bottom of the meatus and divides into filaments for the supply of the crista of the ampulla of the posterior semicircular duct.

The *cochlear nerve* divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus spiralis foraminosus, those for the apical coil through the canalis centralis, and the nerves bend outwards and pass between the lamellæ of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the *spiral ganglion of the cochlea* (ganglion of Corti) (fig. 924), consisting of bipolar nerve-cells from which the fibres of the nerve take origin. Reaching the outer edge of the osseous spiral lamina, the nerve-fibres pass through the foramina in the tympanic lip; some end by arborising around the deep ends of the inner hair-cells, while others pass between Corti's rods and across Corti's tunnel, and end

in a similar manner in relation to the outer hair-cells. The cochlear nerve gives off a vestibular branch to supply the vestibular end of the ductus cochlearis; the filaments of this branch traverse the foramina in the fossa cochlearis (p. 993).

FIG. 924.—Part of the cochlear division of the acoustic nerve. Highly magnified. (Henne.)

Vessels. The arteries of the labyrinth are the internal auditory branch of the basilar artery, and the stylo-mastoid branch of the posterior auricular artery. The internal auditory artery divides at the bottom of the internal acoustic meatus into two branches: cochlear and vestibular. The cochlear branch subdivides into

twelve or fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the lamina spiralis and basilar membrane. The vestibular branches are distributed to the utricle, saccule, and semicircular ducts.

The veins of the vestibule and semicircular canals accompany the arteries, and, receiving the veins of the cochlea at the base of the modiolus, unite to form the internal auditory veins which end in the posterior part of the superior petrosal sinus or in the transverse sinus. A small vein, from the basal turn of the cochlea, traverses the aqueductus cochleæ and joins the internal jugular vein.

Applied Anatomy.—The diseased conditions which may be found in the internal ear usually result from the spread of a suppurative process from the middle ear—thus in

* The nerve sometimes splits on the proximal side of the ganglion, which is then divided into three parts, one on each branch of the nerve. When this occurs the ganglion of the posterior division is placed in the foramen singulare.

chronic suppuration of the latter, destruction of the internal ear may take place, with necrosis of parts of the cochlea or vestibule. Such cases will be associated with 'nerve-deafness,' and the disease may spread by means of the sheaths of the facial and acoustic nerves into the posterior fossa of the skull.

Hæmorrhage occasionally occurs into the labyrinth in certain blood disorders, resulting in complete 'nerve-deafness,' and such conditions may be associated with symptoms known as 'Menière's disease,' vertigo, giddiness, and tinnitus. Nerve-deafness is diagnosed when all 'bone-conduction' of sound is lost, and is most commonly seen in patients suffering from congenital syphilis, many deaf-mutes being the subjects of this condition. It is also not rare after mumps.

PERIPHERAL TERMINATIONS OF NERVES OF GENERAL SENSATIONS

The peripheral terminations of the nerves associated with general sensations (i.e. the muscular sense and the senses of heat, cold, pain, and pressure) are widely distributed throughout the body. These nerves may end as *free fibrils* amongst the tissue elements or in *special end-organs* where the terminal nerve-filaments are enclosed in capsules.

Free nerve-endings occur chiefly in the epidermis and in the epithelium covering certain mucous membranes; they are well seen in the stratified squamous epithelium

FIG. 925.—An end-bulb of Krause. (From Klein's Elements of Histology.)

a. Medullated nerve-fibre. b. Capsule.

FIG. 926.—Tactile corpuscles; (a) of Grandry, (b) of Herbst.

of the cornea, and are also found in the root-sheaths and papillæ of the hairs, and around the bodies of the sudoriferous glands.

When the nerve-fibre approaches its termination, the medullary sheath suddenly disappears, leaving the axis-cylinder surrounded by the neurolemma. After a time the fibre loses its neurolemma, and consists only of an axis-cylinder, which can be seen, in preparations stained with chloride of gold, to be made up of fine varicose fibrillæ. Finally, the axis-cylinder breaks up into its constituent fibrillæ, which often present regular varicosities, and anastomosing with one another, end in small knobs or discs between the epithelial cells.

Under this heading may be classed the *tactile discs* described by Merkel as occurring in the epidermis of the pig's snout, where the fibrillæ of the axis-cylinder end in cup-shaped discs in apposition with large epithelial cells.

The **special end-organs** exhibit great variety in size and shape, but have one feature in common, viz. the terminal fibrils of the nerve are enveloped by a capsule. Included in this group are the end-bulbs of Krause; the corpuscles of Grandry, of Pacini, of Herbst, of Golgi and Mazzoni, of Wagner and Meissner; and the neurotendinous and neuromuscular spindles.

The **end-bulbs of Krause** (fig. 925) are minute cylindrical or oval bodies, consisting of a capsule of connective tissue enveloping a soft semi-fluid core in which the

axis-cylinder terminates either in a bulbous extremity or in a coiled-up plexiform mass. End-bulbs are found in the conjunctiva of the eye (where they are spheroidal in shape in man, but cylindrical in most other animals), in the mucous membrane of the lips and tongue, and in the epineurium of nerve-trunks. They are also found in the penis and clitoris, and have there received the name of *genital corpuscles*; in these situations they have a mulberry-like appearance, being constricted by connective tissue septa into from two to six knob-like masses. In the synovial strata of certain joints (e.g. those of the fingers), rounded or oval end-bulbs occur, and are designated *articular end-bulbs*.

The *tactile corpuscles of Grandry* (fig 926a) occur in the papillæ of the beak and tongue of ducks and geese. Each consists of a capsule composed of a delicate,

FIG. 927.—A Pacinian corpuscle, with its system of capsules and its central cavity.

a. Arterial twig, ending in capillaries, which form loops in some of the intercapsular spaces; one penetrates to the central capsule. b. The fibrous tissue of the stalk. c. Nerve-fibre advancing to the central capsule, there losing its medullary sheath, and passing along the core to the opposite end, where it terminates in a tuberculated enlargement.

of these corpuscles is attached to and encloses the termination of a single nerve-fibre. The corpuscle (which is visible to the naked eye and can be most easily demonstrated in the mesentery of a cat) consists of a number of concentric lamellæ or capsules arranged around a central space, in which the nerve-fibre is contained. Each lamella is composed of bundles of fine connective tissue fibres, and is lined on its inner surface by a single layer of flattened epithelioid cells. The central space is elongated or cylindrical in shape, and filled with a transparent core, in the middle of which the axis-cylinder traverses the space to near its distal extremity, where it ends in one or more small knobs. Todd and Bowman have described minute arteries as entering by the sides of the nerves and forming capillary loops in the intercapsular spaces, and even penetrating into the central space.

Herbst has described a nerve-ending somewhat similar to the Pacinian corpuscle, in the mucous membrane of the tongue of the duck; and in some other situations. It differs, however, from the Pacinian corpuscle in being smaller, in its capsules being more closely approximated, and—especially in the fact that the axis-cylinder

FIG. 928.—A papilla of the hand, containing a tactile corpuscle of Wagner and Meissner. $\times 350$.

nucleated membrane, and containing two or more granular, somewhat flattened cells between which the axis-cylinder ends in flattened discs.

The *Pacinian corpuscles* (fig. 927) are found in the subcutaneous tissue on the nerves of the palm of the hand and sole of the foot, and in the genital organs of both sexes; they also occur on the nerves of the joints, and in some other situations, as in the mesentery and pancreas of the cat and along the tibia of the rabbit. Each

in the central clear space is coated with a continuous row of nuclei. These nerve-endings are known as the *corpuscles of Herbst* (fig. 926b).

The *corpuscles of Golgi and Mazzoni* are found in the subcutaneous tissue of the pulp of the fingers. They differ from Pacinian corpuscles in that their capsules are thinner, their contained cores thicker, and in the latter the axis-cylinders ramify more extensively and end in flat expansions.

The *tactile corpuscles of Wagner and Meissner* (fig. 928) are oval-shaped bodies which occur in the papillæ of the corium of the hand and foot, the front of the forearm, the skin of the lips, the mucous membrane of the tip of the tongue, the palpebral conjunctiva, and the skin of the mammary papilla. Each is enveloped by a connective tissue capsule, which sends membranous septa into the interior.

FIG. 929.—A nerve-ending of Ruffini. (Arch. ital. de Biol., Turin, t. xxi. 1894.)

FIG. 930.—A neurotendinous spindle or organ of Golgi from the human tendo calcaneus. (After Ciaccio.)

The axis-cylinder passes through the capsule, and after making several spiral turns round the body of the corpuscle ends in small globular or pear-shaped enlargements.

Corpuscles of Ruffini.—Ruffini described a special variety of nerve-ending in the subcutaneous tissue of the human finger (fig. 929), and mostly situated at the junction of the corium with the subcutaneous tissue. They are oval in shape, and consist of strong connective tissue sheaths, inside which the nerve-fibres divide into numerous branches, which show varicosities and end in small free knobs.

The *neurotendinous spindles* or *organs of Golgi* are chiefly found near the junctions of tendons with muscles. Each is enclosed in a capsule which contains a number of enlarged tendon-fasciculi (*intrafusal fasciculi*). One or more nerve-fibres perforate the side of the capsule and lose their medullary sheaths; the axis-cylinders subdivide and end between the tendon-fibres in irregular discs or varicosities (fig. 930).

The *neuromuscular spindles* are present in the majority of voluntary muscles, and consist of small bundles of peculiar muscular fibres (*intrafusal fibres*), embryonic in type, invested by capsules, within which nerve-fibres, experimentally shown to be

1008 ORGANS OF THE SENSES AND COMMON INTEGUMENT

sensory, terminate. These neuromuscular spindles vary in length from 0.8 mm. to 5 mm. and have a fusiform appearance. The large medullated nerve-fibres passing to the end-organ are from one to three or four in number; entering the fibrous capsule, they divide several times, and, losing their medullary sheaths,

FIG. 931.—The middle third of a terminal plaque in the muscle-spindle of an adult cat. (After Ruffini.)

ultimately end in naked axis-cylinders encircling the intrafusal fibres by flattened expansions, or irregular ovoid or rounded discs (fig. 931). Neuromuscular spindles have not yet been demonstrated in the muscles of the tongue, and only a few exist in the ocular muscles.

THE COMMON INTEGUMENT

The integument or skin (fig. 932) covers the body and protects the deeper tissues. It contains the peripheral endings of many of the sensory nerves, plays an important part in the regulation of the body temperature, and possesses limited excretory and absorbing powers. It consists principally of a layer of vascular connective tissue, named the *corium* or *cutis vera*, and an external covering of epithelium, termed the *epidermis* or *cuticle*. On the surface of the former layer are sensitive and vascular *papillæ*; and within, or beneath it, are certain organs with special functions: namely, the *sudoriferous* and *sebaceous glands*, and the *hair-follicles*.

The *epidermis* or *cuticle* is non-vascular; it consists of stratified epithelium (fig. 933), and is accurately moulded on the papillary layer of the corium. It varies in thickness in different parts. In some situations, as in the palms of the hands and soles of the feet, it is thick, hard, and horny in texture. This may be in a measure due to the fact that these parts are exposed to intermittent pressure, but that this is not the only cause is proved by the fact that the condition exists to a very considerable extent at birth. The more superficial layers of cells form the *horny layer* (*stratum corneum*), which may be separated by maceration from a deeper stratum, the *stratum mucosum*, consisting of several layers of differently shaped cells. The free surface of the epidermis is marked by a network of linear furrows of variable size, dividing the surface into a number of polygonal or lozenge-shaped areas. These furrows are large opposite the flexures of the joints, and correspond with the folds in the corium produced by movements. In other situations, as upon the back of the hand, they are small, and intersect one another at various angles. Upon the palmar surfaces of the hands and fingers, and upon the soles of the feet, these lines are fine but very distinct, and are disposed in more or less parallel curves; they depend upon the large size and peculiar arrangement of the papillæ upon which the epidermis is placed. In each individual the lines on the tips of the fingers and thumbs form distinct patterns unlike those of any other person. A method of determining the identity of a criminal is based on this fact, impressions ('finger-prints') of these lines being made on paper covered with soot, or on white paper after first covering the fingers with ink. The deep surface of the epidermis is accurately moulded upon the papillary layer of the corium, the papillæ being covered by a basement membrane; so that when the epidermis

is removed by maceration, its under surface presents a number of pits or depressions corresponding with the papillæ, and ridges corresponding with the intervals between them. Fine tubular prolongations are continued from this layer into the ducts of the sudoriferous and sebaceous glands.

The epidermis consists of stratified epithelium which is arranged in five layers named from within outwards as follows: (a) stratum germinativum, (b) stratum mucosum, (c) stratum granulosum, (d) stratum lucidum, and (e) stratum corneum.

FIG. 932.—A diagrammatic section of the skin. Magnified.

The *stratum germinativum* consists of a layer of columnar cells with oblong nuclei. The cells are placed perpendicularly on the basement membrane and attached to it by denticulated extremities.

The *stratum mucosum* is composed of several layers of spherical or polyhedral cells, the contents of which are soft, opaque, and granular. These cells are joined to one another by fine protoplasmic bridges. When the cells are isolated these bridges are broken and the surfaces of the cells are beset with numerous short thorn-like processes which give the cells a characteristic appearance and have led to their being named *prickle-cells*. The cells contain numerous fine fibrils which can be stained by carmine or hæmatoxylin, and are continuous with those of neighbouring cells across the protoplasmic bridges. Between the bridges are minute lymph-channels in which lymph-corpuscles or pigment-granules may be found.

The *stratum granulosum* comprises two or three layers of fusiform cells which contain granules of *eleidin*, a substance readily stained by hæmatoxylin or carmine,

and probably an intermediate stage in the formation of keratin. They are supposed to be cells undergoing transformation from the protoplasmic cells of the stratum mucosum to the horny cells of the superficial layers.

The *stratum lucidum* appears in section as a homogeneous or dimly striated layer, composed of closely packed cells in which traces of flattened nuclei may be found, and in which the eleidin has been changed into a substance named *keratohyalin*.

The *stratum corneum* consists of several layers of horny epithelial cells in which no nuclei are discernible. They are unaffected by acetic acid, and their protoplasm has been converted into a horny material, known as *keratin*. According to Ranvier they contain granules of a material which has the characteristics of beeswax.

The black colour of the skin in the negro and the tawny colour in some of the white races are due to the presence of pigment in the cells of the epidermis. This

FIG. 933.—A section of the epidermis. (Ranvier.)

pigment is more especially distinct in the cells of the stratum mucosum, and is similar to that found in the cells of the pigmentary layer of the retina. As the cells approach the surface and desiccate, the pigment is partially lost.

The *corium* or *cutis vera* is tough, flexible, and highly elastic. It is very thick in the palms of the hands and soles of the feet; thicker on the posterior than on the anterior aspect of the body, and on the lateral than on the medial sides of the limbs. It is exceedingly thin and delicate in the eyelids, scrotum, and penis.

It consists of felted connective tissue, with a varying number of elastic fibres and numerous blood-vessels, lymphatic vessels, and nerves. The connective tissue is arranged in two layers: a deeper or *reticular*, and a superficial or *papillary*. Unstriated muscular fibres are found in the superficial layers of the corium wherever hairs are present; they are also present in the subcutaneous areolar tissue of the scrotum, penis, labia majora, and nipples. In the nipples the fibres are disposed in bands, closely reticulated and arranged in superimposed laminae.

The *reticular layer* consists of strong interlacing bands, composed chiefly of white fibrous tissue, but containing some yellow elastic fibres which vary in number in different parts; the connective tissue corpuscles are often to be found flattened against the bundles of white fibrous tissue. Towards the attached surface the fasciculi are coarse, and the large areolæ left by their interlacement are occupied by adipose tissue and sweat-glands. Below the reticular layer is the subcutaneous areolar tissue, which, except in a few situations, contains fat.

The *papillary layer* consists of numerous highly sensitive and vascular eminences, the *papillæ*, which rise perpendicularly from its surface. The papillæ are minute conical eminences, having round or blunted extremities, occasionally divided into two or more parts, and are received into corresponding pits on the under surface of the cuticle. On the general surface of the body, more especially in parts endowed with slight sensibility, they are few in number, and exceedingly minute; but in some situations, as upon the palmar surfaces of the hands and fingers, and upon the plantar surfaces of the feet and toes, they are large, closely aggregated together, and arranged in parallel curved lines, forming the elevated ridges seen on the free surface of the epidermis. Each ridge contains two rows of papillæ, and between the rows the ducts of the sudoriferous glands pass outwards to open on the summit of the ridge. Each papilla consists of very small and closely interlacing bundles of finely fibrillated tissue, with a few elastic fibres; within this tissue is a capillary loop, and in some papillæ, especially in the palms of the hands and the fingers, there are tactile corpuscles.

The *arteries* supplying the skin form a network in the subcutaneous tissue, and from this network branches are distributed to the sudoriferous glands, the hair-follicles, and the fat. Other branches unite in a plexus immediately beneath the corium; from this plexus, fine capillary vessels pass into the papillæ, forming

FIG. 934.—A longitudinal section through the root of a nail.

a single capillary loop in the smaller papillæ, but in the larger ones dividing into two or more capillary vessels. The *lymphatic vessels* of the skin form a superficial and a deep network, which communicate with each other and with the lymphatic vessels of the subcutaneous tissue by oblique branches.

The *nerves* of the skin terminate partly in the epidermis and partly in the corium; their different modes of ending are described on pp. 1005 to 1007.

The **appendages of the skin** are the nails, the hairs, and the sudoriferous and sebaceous glands with their ducts.

The **nails** (fig. 934) are flattened, elastic structures of a horny texture, placed upon the distal parts of the dorsal surfaces of the terminal phalanges of the fingers and toes. Each is implanted into a groove in the skin by a portion called the *root*; the exposed part is called the *body*, and the distal extremity the *free edge*. The nail is firmly adherent to the corium, being accurately moulded upon its surface; the part of the corium beneath the body and root of the nail is called the *nail-matrix*, because from it the nail is produced. Under the greater part of the body of the nail the matrix is thick, and raised into a series of longitudinal ridges which are very vascular, and the colour is seen through the transparent tissue. Near the root of the nail the papillæ are smaller, less vascular, and have no regular arrangement, and here the tissue of the nail is more opaque; hence this portion is of a white colour, and is called the *lunula* on account of its shape.

As the cuticle passes forwards on the dorsal surface of the finger or toe it is attached to the surface of the nail a little in advance of its root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and the horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The superficial, horny part of the nail consists of a greatly thickened stratum lucidum, the stratum corneum forming merely the thin cuticular fold (*eponychium*) which overlaps the lunula;

the deeper part consists of the stratum mucosum. The cells in contact with the papillæ of the matrix are columnar in form and arranged perpendicularly to the surface; those which succeed them are rounded or polygonal, while the more superficial ones are thin and flat, and so closely packed as to make the limits of the cells very indistinct. The nails grow in length by the proliferation of the cells of the stratum mucosum at the root of the nail, and in thickness from that part of the stratum mucosum which underlies the lunula.

Hairs are found on nearly every part of the surface of the body, but are absent from the palms of the hands, the soles of the feet, the dorsal surfaces of the terminal

FIG. 935.—A section of the skin, showing the epidermis and dermis, a hair in its follicle, the Arrector pili muscle, with sebaceous glands opening into the hair-follicle.

phalanges, the glans penis, the inner surface of the prepuce, and the inner surfaces of the labia. They vary much in length, thickness, and colour in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; the eyelashes, the hairs of the pubic region, and the whiskers and beard are remarkable for their thickness. Straight hairs are stronger than curly hairs and present on transverse section a cylindrical or oval outline: curly hairs, on the other hand, are flat.

A hair consists of a *root*, the part implanted in the skin; and a *shaft* or *scapus*, the portion projecting from the surface.

The *root of the hair* ends in an enlargement, the *hair-bulb*, which is whiter in colour and softer in texture than the shaft, and is lodged in an involution of the epidermis and superficial portion of the dermis, called the *hair-follicle* (fig. 935). When the hair is of considerable length the follicle extends into the subcutaneous

tissue. The hair-follicle commences on the surface of the skin with a funnel-shaped opening, and passes inwards in an oblique or curved direction—the latter in curly hairs—to become dilated at its deep extremity, where it corresponds with the hair-bulb. Opening into the follicle, near its free extremity, are the ducts of one or more sebaceous glands. At the bottom of each hair-follicle is a small conical, vascular eminence or papilla, similar in every respect to those found upon the surface of the skin; it is continuous with the dermic layer of the follicle, and is supplied with nerve-fibrils. The hair-follicle consists of two coats—an outer or *dermic*, and an inner or *epidermic*.

The *outer* or *dermic* coat is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and supplied by numerous minute nervous filaments. It consists of three layers (fig. 936). The most internal is a hyaline

FIG. 936.—A transverse section of a hair-follicle.

basement membrane, which is well marked in the larger hair-follicles, but is not very distinct in the follicles of minute hairs; it is limited to the deeper part of the follicle. Outside this is a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle; this layer extends from the bottom of the follicle to the openings of the ducts of the sebaceous glands. Externally is a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding with the reticular part of the corium; in this are contained the blood-vessels and nerves.

The *inner* or *epidermic* coat is closely adherent to the root of the hair, and consists of two strata named respectively the *outer* and *inner root-sheaths*; the outer root-sheath corresponds with the stratum mucosum of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair-follicle these cells become continuous with those of the root of the hair. The inner root-sheath consists of: (1) a delicate cuticle next the hair, composed of a single layer of imbricated scales with atrophied nuclei; (2) one or two layers of horny, flattened, nucleated cells, known as *Huxley's layer*; and (3) a single layer of cubical cells with clear flattened nuclei, called *Henle's layer*.

The *hair-bulb* is moulded over the papilla and composed of polyhedral epithelial cells, which as they pass upwards into the root of the hair become elongated and spindle-shaped, except those in the centre, which remain polyhedral.

The *shaft of the hair* consists, from within outwards, of the medulla, the cortex, and the cuticle. The *medulla* is usually absent from the fine hairs covering the surface of the body, and commonly from those of the head. When viewed by transmitted light it appears deeper in colour and more opaque than the cortex, but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, with air-spaces between, and sometimes within, the cells. The *cortex* constitutes the chief part of the shaft; its cells are elongated and are united to form flattened fusiform fibres which contain pigment-granules in dark hair, and air in white hair. The *cuticle* consists of a single layer of flat scales which overlap one another from below upwards.

Connected with the hair-follicles are minute bundles of involuntary muscular fibres, termed the *Arrectores pilorum* (fig. 935). They arise from the superficial layer of the corium, and are inserted into the hair-follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side towards which the hair slopes, and by their action diminish the obliquity of the follicle and elevate the hair.* The sebaceous gland is situated in the angle which the arrector muscle forms with the superficial portion of the hair-follicle, and contraction of the muscle thus tends to squeeze the sebaceous secretion out from the duct of the gland.

The **sebaceous glands** (fig. 935) are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, but are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth, and external ear, but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which emerges from a cluster of oval or flask-shaped alveoli, usually from two to five, but in some instances as many as twenty in number. Each alveolus is composed of a transparent basement membrane, enclosing a number of epithelial cells. The outer or marginal cells are small and polyhedral, and are continuous with the cells lining the duct. The remainder of the alveolus is filled with larger cells, containing fat, except in the centre, where the cells are broken up, leaving a cavity filled with their debris and a mass of fatty matter, which constitutes the *sebum cutaneum*. The ducts open most frequently into the hair-follicles, but occasionally upon the general surface, as in the labia minora and the free margins of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much enlarged from the accumulation of pent-up secretion. The tarsal glands of the eyelids are elongated sebaceous glands with numerous lateral diverticula.

The **sudoriferous or sweat glands** are found in almost every part of the skin, and are situated in small pits on the under surface of the corium, or, more frequently, in the subcutaneous tissue, surrounded by a quantity of adipose tissue. Each consists of a single tube, the deep part of which is rolled into an oval or spherical ball, named the *body* of the gland, while the superficial part, or *duct*, traverses the corium and cuticle and opens on the surface of the skin by a funnel-shaped aperture. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or twisted; where the epidermis is thick, as in the palms of the hands and soles of the feet, the part of the duct which passes through it is spirally coiled. The size of the glands varies. They are especially large in those regions where the amount of perspiration is great, as in the axillæ, where they form a thin, manillated layer of a reddish colour, which corresponds exactly with the situation of the hair in this region; they are large also in the groin. Their number varies. They are very plentiful on the palms of the hands, and on the soles of the feet, where the orifices of the ducts are exceedingly regular, and open on the curved ridges; they are least numerous in the neck and back. The tube, both in the body of the gland and in the duct, consists of two layers—an outer, of fine areolar tissue, and an inner of epithelium (fig. 937). The outer layer is thin and is continuous with the superficial stratum of the corium. In the body

* Professor Arthur Thomson of Oxford suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it so that the hair, on emerging through the skin, will be curled. Curved hair-follicles are characteristic of the scalp of the Bushman.

of the gland the epithelium consists of a single layer of cubical cells, between the deep ends of which and the basement membrane is a layer of longitudinally or obliquely arranged non-striped muscular fibres. The ducts are destitute of muscular fibres and are composed of a basement membrane lined by two or three layers of

FIG. 937.—The body of a sudoriferous gland cut in various directions. (From Klein and Noble Smith's Atlas of Histology.)

a. Longitudinal section of the proximal part of the coiled tube. *b.* Transverse section of the same. *c.* Longitudinal section of the distal part of the coiled tube. *d.* Transverse section of the same.

polyhedral cells; the lumen of the duct is coated by a thin cuticle. When the epidermis is carefully removed from the surface of the corium, the ducts may be drawn out in the form of short, thread-like processes on its under surface. The ceruminous glands of the external acoustic meatus are modified sudoriferous glands.

SPLANCHNOLOGY

UNDER this heading are described the respiratory, digestive, and urogenital organs, and the ductless glands.

RESPIRATORY APPARATUS

The respiratory apparatus consists of the larynx, trachea, bronchi, lungs, and pleuræ.

THE LARYNX

The larynx, the organ of the voice, is placed at the upper part of the air-passage. It is situated between the trachea and the root of the tongue, at the upper and anterior part of the neck, where it presents a considerable projection. It forms the lower part of the anterior wall of the pharynx, and is covered behind by the mucous lining of that cavity; on either side of it lie the great vessels of the neck. In the adult male it is situated opposite the fourth, fifth, and sixth cervical vertebræ, but is placed somewhat higher in the female and also during childhood. Symington states that in infants of between six and twelve months of age the tip of the epiglottis is a little above the level of the fibrocartilage between the dens and body of the epistropheus, and that from infancy to adult life the larynx descends for a distance equal to two vertebral bodies and two intervertebral fibrocartilages. The average measurements of the adult larynx are as follows:

	In males.	In females.
Length	44 mm.	36 mm.
Transverse diameter	43 "	41 "
Anteroposterior diameter	36 "	26 "
Circumference	136 "	112 "

Until puberty the larynx of the male differs little in size from that of the female. In the female its increase at puberty is only slight. In the male its increase is considerable; all the cartilages enlarge and the thyroid cartilage projects in the middle line of the neck, while the length of the rima glottidis is nearly doubled.

The larynx is broad above, where it presents the form of a prismatic box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected by ligaments and moved by numerous muscles. It is lined by mucous membrane continuous above and behind with that of the pharynx and below with that of the trachea.

The cartilages of the larynx (fig. 938) are nine in number, three single and three paired, as follows:

Thyroid.	Two Corniculate.
Cricoid.	Two Cuneiform.
Two Arytænoid.	Epiglottis.

The thyroid cartilage is the largest cartilage of the larynx. It consists of two laminae, the anterior borders of which are joined with each other at an angle in the middle line of the neck, and form a subcutaneous projection

named the *laryngeal prominence* (pomum Adami). This prominence is most distinct at its upper part, and is larger in the male than in the female. Immediately above it the laminae are separated by a V-shaped notch, the *superior thyroid notch*.

The *laminae* are irregularly quadrilateral in shape, and their posterior angles are prolonged into processes termed the *superior* and *inferior cornua*. On the *outer surface* of each lamina an *oblique line* runs downwards and forwards from the superior thyroid tubercle situated near the root of the superior cornu, to the inferior thyroid tubercle on the lower border. This line gives attachment to the Sternothyroideus, Thyrohyoideus, and Constrictor pharyngis inferior.

The *inner surface* is smooth: above and behind, it is slightly concave and covered by mucous membrane. In front, in the angle formed by the junction of the laminae, are attached the stem of the epiglottis, the ventricular and vocal ligaments, the Thyrocartyloidei, Thyroepiglottici and Vocales muscles, and the thyroepiglottic ligament.

The *upper border* is concave behind and convex in front; it gives attachment to the corresponding half of the hyothyroid membrane.

The *lower border* is concave behind, and nearly straight in front, the two parts being separated by the inferior thyroid tubercle. A small part of it in and near the middle line is connected to the cricoid cartilage by the middle cricothyroid ligament.

The *posterior border*, thick and rounded, receives the insertions of fibres of the Stylopharyngeus and Pharyngopalatinus muscles. It ends in the superior and inferior cornua. The *superior cornu* is long and narrow, directed upwards, backwards, and medialwards, and ends in a conical extremity, which gives attachment to the lateral hyothyroid ligament. The *inferior cornu* is short and thick: it is directed downwards, with a slight inclination forwards and medialwards, and has, on the medial side of its tip, a small oval facet for articulation with the side of the cricoid cartilage.

The *anterior border* is fused with that of the opposite lamina, forming with it an angle of about 90° in the adult male, and about 120° in the adult female.

During infancy the laminae of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip, named the *intrathyroid cartilage*, which extends from the upper to the lower border of the cartilage in the middle line, and is distinguished from the laminae by being more flexible and transparent.

FIG. 988.—The cartilages of the larynx.
Posterior view.

The **cricoid cartilage** is smaller, but thicker and stronger than the thyroid, and forms the lower and posterior parts of the wall of the larynx. It consists of (a) a posterior quadrate lamina, and (b) a narrow anterior arch.

The *lamina* is deep and broad, and measures vertically from 2 cm. to 3 cm.; on the middle of its posterior surface is a vertical ridge to the upper part of which the two fasciculi of the longitudinal fibres of the œsophagus are attached by a stout tendon (p. 1081); and on either side of the ridge is a broad depression for the origin of the *Cricarytænoides posterior*.

The *arch* is narrow and convex, and measures vertically from 5 mm. to 7 mm.; it affords attachment in front and at the sides to the *Cricothyreoides*, and behind, to part of the *Constrictor pharyngis inferior*.

On either side, at the junction of the lamina with the arch, is a small round facet, directed lateralwards and backwards, for articulation with the inferior cornu of the thyroid cartilage.

The *lower border* of the cricoid cartilage is horizontal, and connected to the highest ring of the trachea by the cricotracheal ligament. The *upper border* runs obliquely upwards and backwards, owing to the great depth of the lamina. It gives attachment, in front, to the middle cricothyroid ligament; at the sides, to the conus of the *Cricarytænoides laterales*; behind, it presents, in the middle, a shallow notch, and on either side of this is a smooth, oval, convex surface, directed upwards and lateralwards, for articulation with the base of an arytenoid cartilage.

The *inner surface* of the cricoid cartilage is smooth, and lined by mucous membrane.

The **arytænoid cartilages** two in number, are situated at the upper border of the lamina of the cricoid cartilage, at the back of the larynx. Each is pyramidal in form, and has three surfaces, a base, and an apex.

The *posterior surface* is triangular, smooth, concave, and gives attachment to the *Arytænoides obliquus* and *transversus*.

The *anterolateral surface* is somewhat convex and rough. On it, near the apex of the cartilage, is a rounded elevation (*colliculus*) from which a crest (*crista arcuata*) curves: at first backwards and then downwards and forwards to the vocal process. The lower part of this crest intervenes between two depressions or foveæ, an upper, triangular, and a lower, oblong in shape; to the upper the ventricular ligament is attached; to the lower, the *Vocalis* and *Cricarytænoides lateralis*.

The *medial surface* is narrow, smooth, and flat; it is covered by mucous membrane, and forms the lateral boundary of the intercartilaginous part of the rima glottidis.

The *base* of each cartilage is convex, and on it is a smooth surface for articulation with the cricoid cartilage. Its lateral angle or *muscular process*, short, rounded, and prominent, projects backwards and lateralwards, and gives insertion to the *Cricarytænoides posterior* behind, and to the *Cricarytænoides lateralis* in front. Its anterior angle or *vocal process* is prominent and pointed; it projects horizontally forwards and gives attachment to the vocal ligaments.

The *apex* of each cartilage curves backwards and medialwards, and is surmounted by the *corniculate cartilage*.

The **corniculate cartilages** (cartilages of Santorini) are two small conical nodules consisting of yellow elastic cartilage, which articulate with the summits of the arytenoid cartilages and serve to prolong them backwards and medialwards. They are situated in the posterior parts of the aryepiglottic folds of mucous membrane, and are sometimes fused with the arytenoid cartilages.

The **cuneiform cartilages** (cartilages of Wrisberg) are two small, elongated pieces of yellow elastic cartilage, placed one on either side, in the aryepiglottic fold, where they give rise to small whitish elevations on the surface of the mucous membrane, just in front of the corniculate cartilages.

The **epiglottis** is a thin lamella of yellow fibrocartilage, shaped like a leaf, and projecting obliquely upwards and forwards behind the root of the tongue, in front of the entrance to the larynx. The free extremity is broad and rounded; the attached part or stem is long, narrow, and connected by an elastic ligament, the *thyreo-epiglottic ligament*, to the angle formed by the two laminae of the thyroid cartilage, a short distance below the superior thyroid

notch. The lower part of its anterior surface is connected to the upper border of the body of the hyoid bone by an elastic filamentous band, the *hyo-epiglottic ligament*.

The *anterior or lingual surface* is covered on its upper, free part by mucous membrane which is reflected on to the sides and root of the tongue, forming a median and two lateral *glosso-epiglottic folds*; the lateral glosso-epiglottic folds are partly attached to the wall of the pharynx. The depressions between the epiglottis and the root of the tongue, on either side of the median fold, are named the *valleculæ* (fig. 942). The lower part of this surface lies behind the hyoid bone, the thyrohyoid membrane, and the upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

FIG. 939.—The ligaments of the larynx. Anteroposterior view.

The *posterior or laryngeal surface* is smooth, concave from side to side, concavoconvex from above downwards; its lower part projects backwards as an elevation, the *tubercle or cushion*. When the mucous membrane is removed, the surface of the cartilage is seen to be indented by a number of small pits, in which mucous glands are lodged. The aryepiglottic folds are attached to the sides of the epiglottis.

Structure.—The corniculate and cuneiform cartilages, the epiglottis, and the apices of the arytenoids at first consist of hyaline cartilage, but later, elastic fibres are deposited in the matrix, converting them into yellow fibrocartilage, which shows little tendency to calcification. The thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, and somewhat later in the cricoid and the arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone.

Ligaments.—The ligaments of the larynx (figs. 939, 940) are (a) *extrinsic*, those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and (b) *intrinsic*, those uniting the cartilages of the larynx to each other.

Extrinsic ligaments.—The thyroid cartilage is connected to the hyoid bone by the hyothyroid membrane, and by a middle and two lateral hyothyroid ligaments.

The *hyothyroid membrane* is a broad, fibro-elastic layer, attached below to the upper border of the thyroid cartilage and to the front of its superior cornu, and above to the upper margin of the posterior surface of the body and greater cornu of the hyoid bone, thus passing behind the posterior surface of the body of the hyoid bone, and being separated from it by a bursa mucosa, which facilitates the upward movement of the larynx during deglutition. The middle, thicker, part of the membrane is termed the *middle hyothyroid*

FIG. 940.—The ligaments of the larynx. Posterior view.

ligament; each of its lateral thinner portions is pierced by the superior laryngeal vessels and the internal branch of the superior laryngeal nerve. Its anterior surface is in relation with the Thyrohyoideus, Sternohyoideus, and Omohyoideus, and with the body of the hyoid bone.

The *lateral hyothyroid ligaments* are round elastic cords which form the posterior borders of the hyothyroid membrane and pass between the tips of the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule, the *cartilago triticea*, is frequently found in each ligament.

An elastic band, the *hyo-epiglottic ligament*, connects the anterior surface of the epiglottis to the upper border of the body of the hyoid bone.

The *cricotracheal ligament* unites the lower border of the cricoid cartilage with the first ring of the trachea. It is continuous below with the fibrous membrane which unites the rings of the trachea to each other.

Intrinsic ligaments.—Beneath the mucous membrane of the larynx is a broad sheet of fibrous tissue containing many elastic fibres, and termed the *elastic membrane of the larynx*. It is subdivided on either side by the interval

between the ventricular and vocal ligaments; the upper portion extends between the arytenoid cartilage and the epiglottis, and is often poorly defined; the lower part is a well-marked membrane forming, with its fellow of the opposite side, the conus elasticus, which connects the thyroid, cricoid, and arytenoid cartilages one to another. The joints between the individual cartilages are also provided with ligaments.

The *conus elasticus* (cricothyroid membrane) is composed mainly of yellow elastic tissue. It consists of an anterior and two lateral portions. The *anterior* part or *middle cricothyroid ligament* is thick and strong, narrow above and broad below. It connects together the front parts of the contiguous margins

FIG. 941.—A sagittal section of the larynx.

of the thyroid and cricoid cartilages. It is overlapped on either side by the Cricothyroideus, but between these muscles it is subcutaneous; it is crossed horizontally by a small arterial arch, formed by the junction of the two cricothyroid arteries; branches of this arch pierce the ligament. The *lateral* portions of the conus elasticus are thinner; they are lined by the mucous membrane of the larynx and covered by the Cricoarytaenoidei laterales and Thyroarytaenoidei. They extend from the inner edge of the superior border of the cricoid cartilage to the inferior margins of the vocal ligaments, with which they are continuous. These ligaments may therefore be regarded as the free borders of the lateral portions of the conus elasticus; they stretch from the vocal processes of the arytenoid cartilages to the angle of the thyroid cartilage about midway between its upper and lower borders.

An *articular capsule*, strengthened posteriorly by a well-marked fibrous band, encloses the arthrodial joint between the inferior cornu of the thyroid and the cricoid cartilage.

Each arytenoid cartilage is connected to the cricoid by an articular capsule and a posterior cricoarytenoid ligament. The *articular capsule* is thin and loose, and is attached to the margins of the articular surfaces. The *posterior crico-arytenoid ligament* extends from the cricoid to the medial and posterior part of the base of the arytenoid.

The *thyreo-epiglottic ligament* is a long, slender, elastic cord which connects the stem of the epiglottis to the angle of the thyroid cartilage below the superior thyroid notch and above the attachment of the ventricular ligaments.

Movements.—The articulations between the inferior cornua of the thyroid cartilage and the cricoid cartilage are diarthrodial, and permit of rotatory and gliding movements. The rotatory movement is one in which the cricoid cartilage rotates upon the inferior cornua of the thyroid cartilage around an axis passing transversely through both joints. The gliding movement consists in a limited shifting of the cricoid on the thyroid in different directions.

The articulations between the arytenoid cartilages and the cricoid cartilage are also diarthrodial, and permit of two varieties of movement: one is a rotation

FIG. 942.—The tongue and the entrance to the larynx, viewed from behind.

of the arytenoid on a vertical axis, whereby the vocal process is moved lateralwards or medialwards, and the rima glottidis increased or diminished; the other is a gliding movement, and allows the arytenoid cartilages to approach or recede from each other: from the direction and slope of the articular surfaces lateral gliding is accompanied by a forward and downward movement. The two movements of gliding and rotation are associated, the medial gliding being connected with medialward rotation, and the lateral gliding with lateralward rotation. The posterior crico-arytenoid ligaments limit the forward movements of the arytenoid cartilages on the cricoid.

Cavum laryngis (figs. 941, 942).—The cavity of the larynx extends from the laryngeal entrance to the lower border of the cricoid cartilage, where it is continuous with the tube of the trachea. It is divided into two parts by the medial projection of the vocal folds, between which is a narrow triangular fissure or chink, the *rima glottidis*. The portion of the cavity above the vocal folds is called the *vestibule*; it is wide above and narrow below; near the centre of its anterior wall is the low backward projection of the tubercle or

cushion of the epiglottis. The ventricular folds project into the lower part of the vestibule, and between them and the vocal folds are the *ventricles* of the larynx. The portion below the vocal folds is elliptical above, but lower down it widens, assumes a circular form, and is continuous with the tube of the trachea.

The *entrance to the larynx* (aditus laryngis) (fig. 942) is triangular, wide in front, narrow behind, and slopes obliquely downwards and backwards. It is bounded, in front, by the epiglottis; behind, by the apices of the arytaenoid cartilages, the corniculate cartilages, and the interarytaenoid notch; and on either side, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the side of the epiglottis and the apex of the arytaenoid cartilage; this is the *aryepiglottic fold*, on the posterior part of the margin of which the cuneiform cartilage forms a more or less distinct whitish prominence, the *cuneiform tubercle*.

The *ventricular folds* (false vocal cords) are two thick folds of mucous membrane, each enclosing a narrow band of fibrous tissue, the *ventricular ligament*, which is fixed in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the anterolateral surface of the arytaenoid cartilage, a short distance above the vocal process. The lower border of this ligament, enclosed in thick mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

The *vocal folds* (true vocal cords) are concerned in the production of sound, and enclose two strong bands, named the *vocal ligaments*. Each ligament consists of a band of yellow elastic tissue, attached in front to the angle of the thyroid cartilage below the ventricular ligament, and behind to the vocal process of the arytaenoid. Its lower border is continuous with the lateral part of the conus elasticus. Its upper border forms the lower boundary of the ventricle of the larynx. Laterally, the Vocalis muscle lies parallel with it. It is covered medially by mucous membrane, which is extremely thin, and closely adherent to it.

The *ventricle of the larynx* is a fusiform fossa on either side, between the ventricular and vocal folds and extending nearly their entire length. The fossa is bounded above, by the free edge of the ventricular fold; below, by the margin of the vocal fold; laterally, by the mucous membrane covering the corresponding Thyreoarytaenoideus. The anterior part of the ventricle leads up by a narrow opening into a pouch of mucous membrane of variable size, called the *appendix*.

The *appendix of the ventricle* (laryngeal saccule) is a membranous sac, placed between the ventricular fold and the inner surface of the thyroid cartilage, occasionally extending as far as the upper border of the cartilage, or even higher; it is conical in form, and curved slightly backwards. On the surface of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the ventricular ligament. Its medial surface is covered by a few delicate muscular fasciculi, which arise from the apex of the arytaenoid cartilage and become lost in the aryepiglottic fold of mucous membrane; laterally it is separated from the thyroid cartilage by

FIG. 943.—A coronal section of the larynx and the upper part of the trachea.

the Thyreoepiglotticus. These muscles compress the sac, and express the secretion it contains upon the vocal fold to lubricate its surfaces.

The *rima glottidis* (fig. 942) is the fissure bounded on either side by the vocal folds in front, and the bases and vocal processes of the arytaenoid cartilages

FIG. 944.—A laryngoscopic view of the interior of the larynx.

behind. It is therefore subdivided into an anterior intermembranous part (glottis vocalis), which measures about three-fifths of the length of the entire aperture, and a posterior intercartilaginous part (glottis respiratoria). Posteriorly it is limited by the mucous membrane passing between the arytaenoid cartilages. The rima glottidis is the narrowest part of the cavity of the larynx, and its level corresponds with the bases of the arytaenoid cartilages. Its length, in the male, is about 23 mm.; in the female from 17 mm. to 18 mm. The width and shape of the rima glottidis vary with the movements of the vocal folds and arytaenoid cartilages during respiration and phonation. In the condition of rest, i.e. when these structures are uninfluenced by muscular action, as in quiet respiration, the intermembranous part is triangular, with its apex in front and its base behind—the latter being represented by a line, about 8 mm. long, connecting the anterior ends of the vocal processes—while the medial surfaces of the arytaenoids are parallel to each other and hence the intercartilaginous part is rectangular. During extreme adduction of the vocal folds, as in the emission of a high note, the intermembranous part of the rima glottidis is reduced to a linear slit by the apposition of the vocal folds; while the intercartilaginous part is triangular, its apex corresponding to the anterior ends of the vocal processes of the arytaenoids, which are approximated by the medial rotation of the cartilages. Conversely in extreme abduction of the vocal folds, as in forced inspiration, the arytaenoids and

FIG. 945.—A side view of the larynx showing the muscular attachments.

their vocal processes are rotated lateralwards, and the intercartilaginous part is triangular in shape but with its apex directed backwards. In this condition the rima glottidis is somewhat lozenge-shaped, the sides of the intermembranous part diverging from before backwards, those of the intercartilaginous part

diverging from behind forwards—the widest part of the aperture corresponding with the attachments of the vocal folds to the vocal processes.

Muscles.—The muscles of the larynx are *extrinsic* and *intrinsic*. The former pass between the larynx and neighbouring structures, and are described in the section on Myology; the latter are confined to the larynx.

The intrinsic muscles are:

Cricothyreoides,
pars obliqua,
pars recta.

Cricoarytænoides posterior.

Cricoarytænoides lateralis.

Arytænoides transversus.

Arytænoides obliquus.

Aryepiglotticus.

Thyrecoarytænoides (externus).

Vocalis.

Thyreopiglotticus.

Ventricularis.

With the exception of the Arytænoides transversus all these muscles are paired.

FIG. 946.—The muscles of the larynx. Posterior view.

FIG. 947.—The muscles of the larynx. Side view. The right lamina of the thyroid cartilage has been removed.

The *Cricothyreoides* (fig. 945), triangular in form, arises from the front and lateral part of the outer surface of the cricoid cartilage; its fibres diverge, and are arranged in two groups. The lower fibres constitute the *pars obliqua*, and slant backwards and lateralwards to the anterior border of the inferior cornu; the anterior fibres form the *pars recta* and run upwards and backwards to the posterior part of the lower border of the lamina of the thyroid cartilage.

The medial borders of the two muscles are separated by a triangular interval occupied by the subcutaneous part of the middle cricothyroid ligament.

The *Cricoarytænoides posterior* (fig. 946) arises from the broad depression on the corresponding half of the posterior surface of the lamina of the cricoid cartilage; its fibres, directed upwards and lateralwards, converge to be inserted into the back of the muscular process of the arytaenoid cartilage. The highest fibres are nearly horizontal, the middle oblique, and the lowest almost vertical.

The *Cricoarytænoides lateralis* (fig. 947) is smaller than the preceding and

of an oblong form. It arises from the upper border of the arch of the cricoid cartilage, and, passing obliquely upwards and backwards, is inserted into the front of the muscular process of the arytenoid cartilage.

The *Arytænoideus transversus* (fig. 946) is a single muscle, filling up the posterior concave surfaces of the arytenoid cartilages. It arises from the posterior surface and lateral border of the arytenoid cartilage of one side, and is inserted into the corresponding parts of the cartilage on the opposite side.

The *Arytænoideus obliquus*, superficial to the *Arytænoideus transversus*, consists of two fasciculi, which cross each other like the limbs of the letter X. Each passes from the base of one arytenoid cartilage to the apex of the other. A few fibres are continued round the lateral margin of the cartilage, and are prolonged into the aryepiglottic fold; they constitute the *Aryepiglotticus* muscle.

The *Thyroarytænoideus* (figs. 947, 948) is a broad, thin muscle, which lies laterally to the vocal fold, the conus elasticus, the ventricle and the ventricular appendix. It arises in front from the lower half of the angle of the thyroid cartilage, and from the middle cricothyroid ligament. Its fibres pass backwards and lateralwards, to be inserted into the base and anterior surface of the arytenoid cartilage. The lower and deeper fibres of the muscle form a triangular band which is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its anterior surface; it is termed the *Vocalis*, and lies parallel with the vocal ligament, to which it is adherent. A considerable number of the fibres of the *Thyroarytænoideus* are prolonged into the aryepiglottic fold, where some of them are lost, while others are continued to the margin of the epiglottis, forming the *Thyroepiglotticus*; the *Thyroepiglottici*, together with the *Aryepiglottici*, are sometimes described as the *Sphincter glottidis*. A few fibres extend along the wall of the ventricle from the

FIG. 948.—Muscles of the larynx, seen from above. (Enlarged.)

lateral margin of the Arytenoid cartilage to the side of the epiglottis, and constitute the *Ventricularis* muscle.

Actions.—The muscles of the larynx may be conveniently divided into two groups, (1) those which open and close the glottis, viz. the *Cricoarytænoidei posteriores* and *laterales* and the *Arytænoidei*; (2) those which regulate the degree of tension of the vocal ligaments, viz. the *Cricothyroidei*, the *Thyroarytænoidei*, and the *Vocales*.

The *Cricoarytænoidei posteriores* open the glottis, by rotating the arytenoid cartilages outwards around a vertical axis passing through the crico-arytenoid joints, so that the vocal processes and the attached vocal folds are separated.

The *Cricoarytænoidei laterales* close the glottis, by rotating the arytenoid cartilages inwards so as to approximate the vocal processes.

The *Arytænoidei* approximate the arytenoid cartilages, and thus close the opening of the glottis, especially at its posterior part.

The *Cricothyroidei* produce tension and elongation of the vocal ligaments by drawing up the arch of the cricoid cartilage and tilting back the upper border of its lamina; the distance between the vocal processes and the angle of the thyroid is thus increased, and the vocal ligaments are consequently elongated.

The *Thyroarytænoidei* draw the arytenoid cartilages forwards towards the thyroid, and thus shorten and relax the vocal ligaments. At the same time they rotate the arytenoid cartilages inwards and approximate the vocal folds. The deeper fibres, forming the *Vocales*, produce relaxation of the vocal ligaments.

The manner in which the entrance of the larynx is closed during deglutition is referred to on p. 1075.

Mucous Membrane.—The mucous membrane of the larynx is continuous above with that of the mouth and pharynx, below with that of the trachea. It covers, and is closely adherent to, the posterior surface and the upper part of the anterior surface of the epiglottis, and forms the aryepiglottic folds which bound the entrance of the larynx. It lines the cavity of the larynx; forms, by its reduplication, the chief parts of the ventricular folds, and is continued from the ventricle into the ventricular appendix. The parts covering the vocal ligaments are thin and intimately adherent to them. On the anterior surface, and the upper half of the posterior surface, of the epiglottis, the upper part of the aryepiglottic folds, and the vocal folds, the epithelium of the mucous membrane is of the stratified squamous type; patches of stratified squamous epithelium are also found above the glottis. The rest of the laryngeal mucous membrane is covered by columnar ciliated epithelium.

Glands.—The mucous membrane of the larynx is furnished with numerous mucous glands; they are very plentiful upon the epiglottis, where they are lodged in little pits; many are present in the margins of the aryepiglottic folds in front of the arytenoid cartilages, where they are termed the *arytenoid glands*. They are large and numerous in the ventricular appendices. The free edges of the vocal folds are devoid of glands.

Taste-buds, similar to those in the tongue, are found over the posterior surface of the epiglottis, in the aryepiglottic folds, and less regularly in some other parts of the larynx.

Vessels and Nerves.—The chief *arteries* of the larynx are the laryngeal branches of the superior and inferior thyroid arteries. The *veins* accompanying the superior laryngeal artery join the superior thyroid vein which opens into the internal jugular vein; those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The *lymphatic vessels* are divisible into two sets, a superior above, and an inferior below, the vocal folds: the superior vessels accompany the superior laryngeal artery, pierce the hyothyroid membrane, and end in the deep cervical lymph-glands situated near the bifurcation of the common carotid artery; some of the inferior lymphatic vessels pierce the middle cricothyroid ligament and open into a lymph-gland lying in front of that ligament or in front of the upper part of the trachea, while others emerge below the cricoid cartilage and pass to the deep cervical lymph-glands and to the lymph-glands alongside of the inferior thyroid artery. The *nerves* are derived from the internal and external branches of the superior laryngeal nerve, from the recurrent nerve and from the sympathetic. The internal laryngeal branch is almost entirely sensory, but some motor filaments are said to be carried by it to the Arytenoideus. It enters the larynx through the posterior part of the hyothyroid membrane above the superior laryngeal artery, and divides into three branches: one is distributed to both surfaces of the epiglottis, a second to the aryepiglottic fold, and a third, the largest, supplies the mucous membrane over the back of the larynx and communicates with the recurrent nerve. The external laryngeal branch supplies the Cricothyroideus by entering its lateral surface. The recurrent nerve passes upwards beneath the lower border of the Constrictor pharyngis inferior immediately behind the cricothyroid joint. It supplies all the intrinsic muscles of the larynx except the Cricothyroideus, and perhaps a part of the Arytenoideus. The sensory branches of the laryngeal nerves form sub-epithelial plexuses, from which fibres pass to end between cells covering the mucous membrane.

THE TRACHEA AND BRONCHI (fig. 949)

The trachea, or windpipe, is a cartilaginous and membranous tube, about 10 cm. long, continued downwards from the lower part of the larynx, and reaching from the level of the sixth cervical vertebra to that of the upper border of the fifth thoracic vertebra, where it divides into two bronchi, one for either lung. It is not quite cylindrical, being flattened posteriorly; its diameter, from side to side, is about 2 cm. in the male and 1.5 cm. in the female. In the child the trachea is smaller, more deeply placed and more movable than in the adult.

Relations.—In the neck its anterior surface is covered from above downwards, by the isthmus of the thyroid gland, the inferior thyroid veins, the *arteria thyroidea ima* (when that vessel exists), the Sternothyroideus and Sternohyoideus muscles, the fascia colli, and, more superficially, by the anastomosing branches between the anterior jugular veins. Laterally it is in relation with the common carotid arteries, the right and left lobes of the thyroid gland, the inferior thyroid arteries, and the recurrent nerves.

In the thorax it lies in the superior mediastinal cavity, and is covered from before backwards by the manubrium sterni, the remains of the thymus, the left innominate vein, the aortic arch, the innominate and left common carotid arteries, and the deep part of the cardiac plexus. Posteriorly it is in contact with the œsophagus. It is in relation on the right side with the pleura and

right vagus, and near the root of the neck with the innominate artery; on the left side with the left recurrent nerve, the aortic arch, and the left common carotid and subclavian arteries (fig. 954).

The right bronchus, wider, shorter, and more vertically directed than the left, is about 2.5 cm. long, and enters the right lung nearly opposite the fifth thoracic vertebra. The azygos vein arches over it from behind; and the right pulmonary artery lies at first below and then in front of it. About

FIG. 949.—A front view of the cartilages of the larynx, trachea, and bronchi.

2 cm. from its commencement it gives off a branch to the upper lobe of the right lung; this is termed the *eparterial branch*, because it arises above the right pulmonary artery. The bronchus now passes below the artery, and is known as the *hyparterial branch*; this divides into two branches for the middle and lower lobes of the lung.

The left bronchus, narrower than the right, is nearly 5 cm. long, and enters the root of the left lung opposite the sixth thoracic vertebra. It passes beneath the aortic arch, and crosses in front of the oesophagus, the thoracic duct, and the descending aorta; the left pulmonary artery lies at first above, and then in front of it. The left bronchus has no *eparterial branch*, and therefore

it has been supposed by some that there is no upper lobe to the left lung, and that the so-called upper lobe corresponds to the middle lobe of the right lung.

The further subdivision of the bronchi will be considered with the structure of the lung.

If the trachea be cut across a short distance above its bifurcation, and the interior of the lower part viewed from above (fig. 950), it will be seen that, in most cases, the septum between the two bronchi lies on the left of the median plane, and the right bronchus appears to be a more direct continuation of the trachea than the left.

FIG. 950.—A transverse section of the trachea, just above its bifurcation.

A solid body dropping into the trachea would naturally be directed towards the right bronchus. This tendency is aided by the larger diameter of the right tube as compared with its fellow. These facts serve to explain why a foreign body in the trachea usually falls into the right bronchus.

Structure (fig. 951).—The trachea and extrapulmonary bronchi consist of a framework of imperfect rings of hyaline cartilage, united by fibrous and unstriped muscular tissue. They are lined by mucous membrane.

The cartilages of the trachea vary from sixteen to twenty in number. Each is an imperfect ring which occupies the anterior two-thirds or so of the circumference of the trachea;

FIG. 951.—A transverse section of the trachea.

are deficient, the tube is completed by fibrous tissue and unstriped muscular fibres. The cartilages are placed horizontally above one another, and are separated by narrow intervals. They measure about 4 mm. in depth and 1 mm. in thickness; their external surfaces are flattened in a vertical direction, but their internal are convex. Two or more of the cartilages often unite, partially or completely, and they are sometimes bifurcated at their extremities. They are highly elastic, but may become calcified in advanced life. In the right bronchus the cartilages vary in number, from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea, but have the same shape and arrangement. The first and the last tracheal cartilages differ from the others (fig. 949).

The first cartilage is broader than the rest, and often divided at one end; it is connected by the cricotracheal ligament with the lower border of the cricoid cartilage, with which, or with the succeeding cartilage, it is sometimes blended.

The last cartilage is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-

shaped process which curves downwards and backwards between the two bronchi. It forms on each side an imperfect ring which encloses the commencement of the bronchus. The cartilage above the last is somewhat broader at its centre than the others.

The fibrous membrane.—The cartilages are enclosed in an elastic fibrous membrane, which consists of two layers, one, the thicker, passing over the outer surfaces of the rings, the other over the inner surfaces: at the upper and lower margins of the cartilages the two layers blend and form a stout membrane which connects the rings one with

another. Where the cartilages are deficient posteriorly the membrane forms a single layer.

The *muscular tissue* is placed within the fibrous membrane at the posterior part of the tube, and consists of two layers of non-striped muscle, longitudinal and transverse. The *longitudinal fibres* are external, and consist of a few scattered bundles. The *transverse fibres* (Trachealis muscle) are internal, and form a thin layer which not only extends between the ends of the cartilages but also passes across in the intervals between the cartilages.

Mucous Membrane.—The mucous membrane is continuous above with that of the larynx, and below with that of the bronchi. It consists of areolar and lymphoid tissue, and presents a well-marked basement membrane, supporting a stratified epithelium, the surface layer of which is columnar and ciliated, while the deeper layers consist of oval or rounded cells. Beneath the basement membrane there is a layer of longitudinal elastic fibres with a small amount of intervening areolar tissue. The *submucous layer* is composed of a loose meshwork of connective tissue, containing large blood-vessels, nerves, and mucous glands; the ducts of the latter pierce the overlying layers and open into the trachea (fig. 951).

Vessels and Nerves.—The trachea is supplied with blood mainly by the inferior thyroid arteries. The veins end in the thyroid venous plexus. The nerves are derived from the vagi and the recurrent nerves, and from the sympathetic trunks; they are distributed to the Trachealis muscle and between the epithelial cells.

Applied Anatomy.—Foreign bodies often find their way into the air-passages, and may consist of large soft substances, as pieces of meat, which may become lodged in the entrance of the larynx, or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air-passages below the obstruction, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry or plum stones, small pieces of bone, buttons, &c., may find their way through the rima glottidis into the trachea or bronchi, or may lodge in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon reflex spasm of the glottis produced by the irritation of the foreign body. When lodged in the ventricle of the larynx the foreign body may produce few symptoms, beyond sudden loss of voice or alteration in the voice sounds. When, however, it is situated in the trachea, it is constantly striking against the vocal folds during expiratory efforts, and thus produces attacks of dyspnoea from spasm of the glottis. When lodged in the bronchus, it usually becomes fixed there, and, occluding the lumen of the tube, causes a loss of the respiratory murmur on the affected side, and may subsequently lead to purulent bronchitis and gangrene of the lung. Foreign bodies should always be removed from the air passages as soon as possible.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue, which is liable to become much swollen from effusion in inflammatory affections, constituting the condition known as 'œdema of the glottis.' This effusion does not extend below the level of the vocal folds, on account of the fact that the mucous membrane is closely adherent to these structures without the intervention of any submucous tissue. In cases of œdema of the glottis, in which it is necessary to open the air-passages to prevent suffocation, the operation of laryngotomy is sufficient. Laryngeal or glottidean œdema may be secondary to some local inflammatory affection such as acute septic laryngitis, syphilitic laryngeal perichondritis, or malignant disease; or the œdema may be passive (non-inflammatory), consequent upon renal or cardiac mischief, angioneurotic œdema.

Ulceration of the larynx may occur from syphilis, either as a superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air-passages may be opened in three different situations: by a vertical incision through the centre of the thyroid cartilage (*thyrotomy*); through the middle cricothyroid ligament (*laryngotomy*); or in some part of the trachea (*tracheotomy*).

Thyrotomy is usually performed for the purpose of removing growths from the vocal folds or for extracting foreign bodies from the ventricle of the larynx. A median incision is made from the upper border of the body of the hyoid bone to the lower border of the cricoid cartilage, and is carried through the subcutaneous tissues and deep fascia between the margins of the Sternohyoidæ. An incision is then made in the middle cricothyroid ligament, and one blade of a stout, sharp-pointed pair of scissors is introduced beneath the lower border of the thyroid cartilage, and this structure is divided from below upwards. Great care must be taken to cut exactly in the middle line to avoid wounding the vocal folds. If the halves of the cartilage are now drawn apart, a very good view of the interior of the larynx will be obtained.

Laryngotomy is a simple operation, and should be performed in those cases where the air-passages require to be opened in an emergency for the relief of some sudden obstruction to respiration. The middle cricothyroid ligament is very superficial, being covered only by the skin, superficial fascia, and the deep fascia in the middle line. On either side it is also covered by the Sternohyoidæus and Sternothyroidæus, which diverge from each other at their upper parts, leaving a slight interval between them. On

these muscles rest the anterior jugular veins. The cricothyroid artery crosses the middle cricothyroid ligament, and may be wounded, but rarely gives rise to any trouble. The operation is performed thus: the head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the cricothyroid depression felt for. A vertical incision is then made through the skin in the middle line over this spot, and carried down through the fascia until the middle cricothyroid ligament is exposed. A cross-cut is then made through the ligament close to the upper border of the cricoid cartilage, so as to avoid, if possible, the cricothyroid artery, and a laryngotomy tube inserted. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut through the superficial structures, and thus to open at once the air-passages. It will be seen, however, that in operating in this way the anterior jugular veins are in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid gland, or this structure may be divided and the trachea opened behind it. From the relations already described it must be evident that the trachea can be more readily opened above than below the isthmus.

Tracheotomy above the isthmus is performed thus: the patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon standing on the right side of his patient makes an incision from 1 cm. to 5 cm. long in the median line of the neck from the top of the cricoid cartilage. After the superficial structures have been divided, the interval between the Sternohyoidei must be found, the fascia divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downwards in the middle line. It has been recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downwards with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forwards in order to steady it, and is then opened by inserting the knife into it and dividing the upper two or three rings by cutting upwards. If the trachea is to be opened beneath the isthmus of the thyroid gland, the incision must be made from a little below the cricoid cartilage to the top of the sternum; in this situation the trachea is situated more deeply.

A portion or the whole of the larynx may be removed for malignant disease. It may be removed by a median incision through the soft parts, freeing the cartilages from the muscles and other structures in front, separating the larynx from the trachea below, and dissecting it off from the deeper structures from below upwards.

THE PLEURÆ

Each lung is invested by a delicate serous membrane, the **pleura**, which is arranged in the form of a closed invaginated sac. A portion of the serous membrane covers the surface of the lung and dips into the fissures between its lobes; it is called the *pulmonary pleura*. The rest of the membrane lines the inner surface of the chest-wall, covers the Diaphragm, and is reflected over the structures occupying the middle of the thorax; this portion is termed the *parietal pleura*. The two portions are continuous with one another round and below the root of the lung; in health they are in actual contact, but the potential space between them is known as the *pleural cavity*. When the lung collapses or when air or fluid collects between the two portions the cavity becomes apparent. The right and left pleural sacs are distinct from one another, and only touch each other for a short distance in front, opposite the second and third pieces of the sternum. The interval between the two sacs is termed the mediastinal cavity. The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Pulmonary pleura.—The *pulmonary pleura* is inseparably connected with the lung. It covers the surfaces of the lung, including those which bound the fissures between the lobes of the lung; it is wanting only at an area where the lung root enters and along a line extending downwards from this and marking the attachment of the pulmonary ligament.

Parietal pleura.—Different portions of the parietal pleura have received special names, which indicate their positions; that lining the inner surfaces of the ribs and Intercostales is the *costal pleura*; that clothing the thoracic surface of the Diaphragm is the *diaphragmatic pleura*; that which ascends into the neck over the summit of the lung is the *cupula of the pleura*; and that which is applied to the other thoracic viscera is the *mediastinal pleura*.

Costal pleura (figs. 952, 953).—The costal pleura lines the ribs and intercostal muscles, and is easily separated from them. In front it begins behind the sternum where it is continuous with the mediastinal pleura. The line of junction of the two parts extends from behind the sternoclavicular joint downwards and medialwards to reach a point in the middle line behind the sternal angle. From this point the line differs on the two sides. On the right side it is continued down to the posterior surface of the xiphoid process. On the left it descends to the level of the fourth or the upper border of the fifth costal cartilage and then diverges lateralwards and is continued down close to the lateral margin of the sternum to the level of the sixth costal cartilage. On

FIG. 952.—A front view of the thorax, showing the relations of the pleuræ and lungs to the chest wall.

Pleuræ in blue ; lungs in purple.

either side the costal pleura sweeps lateralwards, lining the inner surfaces of the costal cartilages, ribs and Intercostales, and at the back of the thorax passes over the sympathetic trunk and its branches, and on to the sides of the bodies of the vertebræ, where it again becomes continuous with the mediastinal pleura. Above, the costal pleura is continuous with the cupula of the pleura at the inner margin of the first rib. Below, it is continuous with the diaphragmatic pleura along a line which differs slightly on the two sides. On the right side the line begins behind the xiphoid process, and runs downwards and backwards behind the seventh costal cartilage, and reaches the mid-axillary line at the level of the tenth rib ; from here the line ascends somewhat to reach the level of the spinous process of the twelfth thoracic vertebra. On the left side the line follows at first the ascending part of the sixth costal cartilage, but in the rest of its course is slightly lower than that on the right side.

Diaphragmatic pleura.—The diaphragmatic pleura is thin, and covers the upper surface of its corresponding side of the Diaphragm. The outer part of its circumference is the line described above, along which it is continuous with the costal pleura. Medially it is continuous with the mediastinal pleura along the line of attachment of the pericardium to the Diaphragm.

Cupula of the pleura.—This, the cervical portion of the pleura, is the continuation of the costal pleura over the apex of the lung. It begins along the inner border of the first rib and extends medialwards and upwards to the apex of the lung; it then descends along the side of the trachea to become continuous with the mediastinal pleura. The cupula of the pleura is strengthened by a dome-like expansion of fascia (*Sibson's fascia*) attached in front to the inner border of the first rib and behind to the anterior border of the transverse process of the seventh cervical vertebra; it is covered and strengthened by a few spreading muscular fibres derived from the Scaleni.

Mediastinal pleura.—The mediastinum or middle portion of the thorax contains the heart, enclosed in its pericardium, the great vessels entering and leaving the heart, and the œsophagus together with other structures described on p. 1035. Over these is placed the mediastinal pleura. Above, it is continuous with the cupula of the pleura; below, with the diaphragmatic pleura; in front and behind, with the costal pleura. Its arrangement is complicated by the fact that the structures forming the root of the lung (viz. bronchus, pulmonary vessels, &c.) carry forward this part of the pleura to the surface of the lung. Above the root of the lung the mediastinal pleura is a continuous sheet between the sternum and vertebral column. At the root of the lung it is carried lateralwards as a tube of serous membrane enclosing the structures of the lung-root and passing into continuity with the pulmonary pleura. Below the lung-root the mediastinal pleura extends as a bilaminar layer from the side of the pericardium to the mediastinal surface of the lung, where it is also continuous with the pulmonary pleura. This bilaminar layer is continuous above with the tube investing the lung root; below it ends in a free falciform border. It is named the *pulmonary ligament*, and serves to retain the lower part of the lung in position.

The inferior limit of the pleura is on a considerably lower level than the corresponding border of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the chest-wall to the Diaphragm the latter is in direct contact with the rib cartilages and the *Intercostales interni*. Moreover, in ordinary inspiration the thin inferior margin of the lung does not extend as low as the line of the pleural reflection, with the result that the costal and diaphragmatic pleuræ are here in contact, the intervening narrow slit being termed the *phrenicocostal sinus*.

FIG. 953.—A lateral view of the thorax, showing the relations of the pleuræ and lungs to the chest wall.

Pleuræ in blue; lungs in purple.

A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is called the *costomediastinal sinus*.

Structure.—The free surface of the pleura is smooth, and moistened by serous fluid. Like other serous membranes, it is covered by a single layer of flattened nucleated cells, united at their edges by cement substance. These cells are modified connective tissue corpuscles, and rest on a basement membrane. Beneath the basement membrane there are networks of yellow elastic and white fibres, imbedded in ground substance which also contains connective tissue cells. Blood-vessels, lymphatics, and nerves are distributed in the substance of the pleura, and the lymphatics communicate with the pleural cavity by means of stomata or openings between the flattened cells.

Vessels and Nerves.—The arteries of the pleura are derived from the intercostal, internal mammary, musculophrenic, thymic, pericardiac, and bronchial vessels. The veins correspond to the arteries. The lymphatics are described on p. 739. The nerves are derived from the phrenic nerve and from the sympathetic trunk. Kölliker states that nerves accompany the ramifications of the bronchial arteries in the pulmonary pleura.

Applied Anatomy.—Acute inflammation of the pleura, or *pleurisy*, may be either dry or wet, and, if wet, either serous or purulent. *Dry pleurisy* is common in pneumonia, and is often an early manifestation of tuberculosis. It gives rise to much pain, and to friction sounds due to the scraping to and fro over one another of the inflamed and roughened parietal and pulmonary pleurae. *Wet pleurisy* occurs if the inflammation causes the effusion of serum into the pleural cavity. The two pleural layers are now separated by the fluid effusion, so the friction sounds are no longer produced. Room is found for the fluid by shrinkage of the supernatant lung due to the retraction of its elastic tissue, and later, when the quantity of serum exceeds about 1·5 litre, by shifting over of the heart and unaffected lung towards the sound side. This shifting may be so extensive that the apex beat of the heart comes to lie under the right mammary papilla. Any pleural effusion that is large enough to embarrass respiration seriously, or has remained unabsorbed for two or three weeks, should be removed by tapping (paracentesis thoracis). The trocar is pushed through the chest-wall into the fluid, in the sixth or seventh intercostal space in the midaxillary line, or in the eighth or ninth space just outside the angle of the scapula. Aspiration is then performed, and as much fluid as possible drawn off: it must be stopped, however, if the patient shows signs of collapse, or if fits of coughing occur and threaten to wound the expanding lung against the sharp end of the trocar. Non-inflammatory or passive effusion into the pleura, called *hydrothorax*, is often seen in the later stages of chronic renal or cardiac disease, and demands treatment on lines similar to the above.

Purulent pleural effusion, or *empyema*, often occurs after such diseases as pneumonia or measles. This condition requires drainage of the cavity, which usually necessitates excision of a portion of a rib. An incision is made down to the seventh or eighth rib in the mid- or posterior axillary line and the periosteum is incised, and separated from the body of the rib, carrying with it the structures in the costal groove. With bone-cutting forceps about 4 cm. or 5 cm. of the rib are separated and removed, and the underlying pleura is incised. The pus having been evacuated, a large drainage tube is inserted into the cavity. The pleura should never be irrigated, as sudden death has followed this proceeding, and great care should be taken to prevent the tube from slipping into the cavity, an occurrence which is far from uncommon.

Pneumothorax, or the presence of gas in the pleural cavity, is a common terminal event in tuberculosis of the lungs; less often it is due to trauma—rupture of the lung, for example, when the chest is crushed, or tearing of the lung-tissue by the sharp projecting end of a broken rib. Air escapes from the lung into the pleural cavity; the elastic tissue of the lung at once contracts, and finally that organ shrinks away to a dark rounded mass the size of a fist, lying close against the vertebral column. The symptoms of pneumothorax are often very severe; cyanosis, intense dyspnoea, great pain on the affected side, and cardiac failure. Their severity is increased by the fact that the blood-vessels of the collapsed lung offer less resistance to the circulation of the blood than do those of the other lung. Not only, therefore, does the sound lung suddenly have to take over the work—the aeration of the blood—normally performed by both lungs, but it has to do so at the moment when the circulation of blood through it is partially short-circuited by the collapsed lung. If the patient survives for a few days, empyema often complicates the pneumothorax, setting up the condition called *pyopneumothorax*. During the last few years a valuable method of treating selected cases of pulmonary tuberculosis by the establishment and maintenance of an artificial pneumothorax on the affected side, causing collapse of the diseased lung, has been employed.

In operations upon the kidney, it must be borne in mind that the pleural cavity usually extends below the level of the medial portion of the last rib, and may therefore be opened in these operations, especially when the last rib is removed in order to give more room.

THE MEDIASTINAL CAVITY

The **mediastinal cavity** is the space between the right and left pleuræ. It extends from the sternum in front to the vertebral column behind, and contains all the thoracic viscera except the lungs. The cavity may be divided for purposes of description into two parts: an upper, the *superior mediastinal cavity*, above the pericardium, and a lower, which is subdivided into three parts, viz.: that in front of the pericardium, the *anterior mediastinal cavity*; that containing the pericardium and its contents, the *middle mediastinal cavity*; and that behind the pericardium, the *posterior mediastinal cavity*.

FIG. 954.—A transverse section through the thorax at the level of the upper margin of the second thoracic vertebra. (Braune.)

The **superior mediastinal cavity** (fig. 954) lies between the manubrium sterni in front, and the upper four thoracic vertebrae behind. It is bounded below by a slightly oblique plane passing from the junction of the manubrium and body of the sternum to the lower part of the body of the fourth thoracic vertebra, and laterally by the pleuræ; above, by the plane of the thoracic inlet. It contains the origins of the Sternohyoidei and Sternothyroidei and the lower ends of the Longi colli; the aortic arch; the innominate artery and the thoracic portions of the left common carotid and the left subclavian arteries; the innominate veins and the upper half of the superior vena cava; the left first intercostal vein; the vagus, cardiac, phrenic, and left recurrent nerves; the trachea, œsophagus, and thoracic duct; the remains of the thymus, and some lymph-glands.

The **anterior mediastinal cavity** (fig. 955) exists only on the left side where the left pleura diverges from the mid-sternal line. It is bounded in front by the sternum, laterally by the pleuræ, and behind by the pericardium. It is narrow above, but widens out a little below. Its anterior wall is formed by the left Transversus thoracis muscle and the fifth, sixth, and seventh left costal cartilages. It contains a quantity of loose areolar tissue, some lymphatic vessels which ascend from the convex surface of the liver, two or three anterior mediastinal lymph-glands, and the small mediastinal branches of the internal mammary artery.

The **middle mediastinal cavity** (fig. 955) is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, the terminal part of the azygos vein, the bifurcation of the trachea, the two bronchi, the pulmonary artery dividing into its right and left branches, the right and left pulmonary veins, the phrenic nerves, and some tracheobronchial lymph-glands.

The **posterior mediastinal cavity** (figs. 955, 956) is an irregularly shaped space running parallel with the vertebral column; it is bounded in front by the pericardium above, and by the posterior surface of the Diaphragm below,

FIG. 955.—A diagram of a transverse section of the thorax, showing the contents of the middle and posterior mediastinal cavities.

behind by the vertebral column from the lower border of the fourth to the twelfth thoracic vertebra, and on either side by the mediastinal pleura. It contains the thoracic part of the descending aorta, the azygos, hemiazygos, and accessory hemiazygos veins, the vagus and splanchnic nerves, the œsophagus, the thoracic duct, and some lymph-glands.

Applied Anatomy.—Primary tumours of the mediastinum are usually sarcoma or carcinoma arising from the thymus or the mediastinal lymph-glands. Lymphosarcoma, embryoma, and dermoid cysts occur more rarely. These tumours give rise to pain, deformity of the chest, and symptoms of pressure on the nerves, blood-vessels, air-passages, lymphatics, and on the œsophagus, as these various structures pass through the thorax. They may produce physical signs very much like those of an aortic aneurysm, so that diagnosis between the two is often difficult. The prognosis is bad, the condition usually proving fatal within a few months or a year of the onset of the symptoms.

Inflammation of the mediastinum due to wounds, or to the spread of inflammation from adjacent parts (e.g. the œsophagus, the pericardium), is sometimes acute, leading to abscess-formation. A more chronic form associated with adhesions and inflammation of the pericardium—the so-called chronic adhesive mediastinopericarditis—gives rise to obscure symptoms suggesting gradual heart-failure, and leads to death slowly but surely,

FIG. 956.—The superior, middle and posterior mediastinal cavities, viewed from the left side.

THE LUNGS (PULMONES)

The lungs are the essential organs of respiration ; they are two in number, placed one on either side within the thorax, and separated from each other by the heart and other contents of the mediastinal cavity (fig. 957). The substance of the lung is of a light, porous, spongy texture ; it floats in water, and crepitates when handled, owing to the presence of air in its alveoli ; it is also highly elastic ; hence the retracted state of these organs when they are removed from the closed cavity of the thorax. The surface is smooth, shining, and marked out into numerous polyhedral areas, indicating the lobules of the organ ; each of these areas is crossed by numerous lighter lines.

At birth the lungs are pinkish-white in colour ; in adult life the colour is a dark slaty-grey, mottled in patches ; and as age advances, this mottling assumes a black colour. The colouring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the

organ ; it increases in quantity as age advances, and is more abundant in males than in females. As a rule, the posterior border of the lung is darker than the anterior.

The right lung usually weighs about 625 gm., the left 567 gm., but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being, in the former, as 1 to 37, in the latter as 1 to 43.

Each lung is conical in shape, and has an apex, a base, three borders, and two surfaces.

The *apex* is rounded, and extends into the root of the neck, reaching from 3 cm. to 4 cm. above the level of the sternal end of the first rib. A sulcus

FIG. 957.—A front view of the heart and lungs.

runs upwards and lateralwards immediately below the apex ; on the right lung this sulcus is produced by the innominate artery, on the left by the subclavian artery.

The *base* is broad, concave, and rests upon the convex surface of the Diaphragm, which separates the right lung from the right lobe of the liver, and the left lung from the left lobe of the liver, the stomach, and the spleen. Since the Diaphragm extends higher on the right than on the left side, the concavity on the base of the right lung is deeper than that on the left. Laterally and behind, the base is bounded by a thin, sharp margin which projects for some distance into the phrenicocostal sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragm.

The *costal surface* is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, which is deeper behind than in front. It is in contact with the costal pleura, and exhibits, in specimens which have been hardened *in situ*, slight grooves corresponding with the overlying ribs.

The *mediastinal surface* is in contact with the mediastinal pleura. On it is a deep concavity, the *cardiac impression*, which accommodates the pericardium; this concavity is larger and deeper on the left than on the right lung, because the heart projects farther to the left than to the right side of the median plane. Above and behind this concavity is a triangular depression named the *hilum*, where the structures which form the root of the lung (p. 1041) enter and leave the viscus. These structures are invested by pleura, which, below the hilum and behind the pericardial impression, forms the pulmonary ligament. On the *right lung* (fig. 958), immediately above the hilum, is an arched furrow which accommodates the azygos vein; while running upwards, and then arching lateralwards some little distance below the apex, is a wide

FIG. 958.—The mediastinal surface of the right lung.

groove for the superior vena cava and right innominate vein; behind this, and nearer the apex, is a furrow for the innominate artery. Behind the hilum and the attachment of the pulmonary ligament is a vertical groove for the œsophagus; this groove becomes less distinct below, owing to the inclination of the lower part of the œsophagus to the left of the middle line. In front and to the right of the lower part of the œsophageal groove is a deep concavity for the extrapericardiac portion of the thoracic part of the inferior vena cava. On the *left lung* (fig. 959), immediately above the hilum, is a well-marked curved furrow produced by the aortic arch, and running upwards from this towards the apex is a groove accommodating the left subclavian artery; a slight impression in front of the latter and close to the margin of the lung lodges the left innominate vein. Behind the hilum and pulmonary ligament is a vertical furrow produced by the descending aorta; and in front of this, near the base of the lung, the lower part of the œsophagus causes a shallow impression.

The *inferior border* is thin and sharp where it separates the base from the costal surface and extends into the phrenicocostal sinus; medially, where it

divides the base from the mediastinal surface, it is blunt and rounded. The *posterior border* is broad and rounded, and is received into the deep concavity on either side of the vertebral column. It is much longer than the anterior border, and projects, below, into the phrenicocostal sinus.

The *anterior border* is thin and sharp, and overlaps the front of the pericardium; that of the *right lung* is almost vertical, and projects into the costo-mediastinal sinus; that of the *left* presents, below, an angular notch, the *cardiac notch*, in which the pericardium is exposed. Opposite this notch the anterior margin of the left lung is situated some little distance laterally to the line of reflection of the corresponding part of the pleura.

Fissures and lobes of the lungs.—The *left lung* is divided into two lobes, an upper and a lower, by a fissure which extends from the costal to the medi-

FIG. 959.—The mediastinal surface of the left lung.

astinal surface of the lung both above and below the hilum. As seen on the surface, this fissure begins on the mediastinal surface of the lung at the upper and posterior part of the hilum, and runs backwards and upwards to the posterior border, which it crosses at a point about 6 cm. below the apex. It then extends downwards and forwards over the costal surface, and reaches the lower border a little behind its anterior extremity, and its further course can be followed upwards and backwards across the mediastinal surface as far as the lower part of the hilum. The *superior lobe* lies above and in front of this fissure, and includes the apex, the anterior border, and a considerable part of the costal surface and the greater part of the mediastinal surface of the lung. The *inferior lobe*, the larger of the two, is situated below and behind the fissure, and comprises almost the whole of the base, a large portion of the costal surface, and the greater part of the posterior border.

The *right lung* is divided into three lobes, superior, middle, and inferior, by two fissures. One of these separates the inferior from the middle and superior lobes, and corresponds closely with the fissure in the left lung. Its direction

is, however, more vertical, and it cuts the lower border about 7.5 cm. behind its anterior extremity. The other fissure separates the superior from the middle lobe. It begins in the previous fissure near the posterior border of the lung, and, running horizontally forwards, cuts the anterior border on a level with the sternal end of the fourth costal cartilage; on the mediastinal surface it may be traced backwards to the hilum. The *middle lobe* of the right lung is small and wedge-shaped, and includes the lower part of the anterior border and the anterior part of the base of the lung.

The right lung, although shorter by 2.5 cm. than the left, in consequence of the Diaphragm rising higher on the right side to accommodate the liver, is broader, owing to the inclination of the heart to the left side; its total capacity and weight are greater than those of the left lung.

Roots of the lungs.—A little above the middle of the mediastinal surface of each lung, and nearer its posterior than its anterior border, is the root of the lung, by which the lung is united to the heart and the trachea. The root is formed by the bronchus, the pulmonary artery, the two pulmonary veins, the bronchial arteries and veins, the pulmonary plexuses of nerves, lymphatic vessels, bronchial lymph-glands, and areolar tissue, all of which are enveloped by pleura. The roots of the lungs lie opposite the bodies of the fifth, sixth and seventh thoracic vertebrae. That of the right lung lies behind the superior vena cava and part of the right atrium of the heart, and below the azygos vein. That of the left lung is below the aortic arch and in front of the descending aorta. The following relations are common to the two lung-roots, viz.: in front, the phrenic nerve, the pericardiophrenic artery and vein, and the anterior pulmonary plexus; behind, the vagus and posterior pulmonary plexus; below, the pulmonary ligament.

The chief structures composing the root of each lung are arranged in a similar manner from before backwards on both sides, viz.: the upper of the two pulmonary veins in front; the pulmonary artery in the middle; and the bronchus behind, with the bronchial vessels on its posterior aspect. Their arrangement differs from above downwards on the two sides; on the right side their position is—*eparterial* bronchus, pulmonary artery, *hyparterial* bronchus, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins. The lower of the two pulmonary veins is situated below the bronchus, at the apex or lowest part of the hilum (figs. 958, 959).

Divisions of the bronchi.—Just as the lungs differ from each other in the number of their lobes, so the bronchi differ in their mode of subdivision.

The *right* bronchus gives off, about 2.5 cm. from the bifurcation of the trachea, a branch for the superior lobe. This branch arises above the level of the pulmonary artery, and is therefore named the *eparterial bronchus*. All the other divisions of the main stem come off below the pulmonary artery, and are consequently termed *hyparterial bronchi*. The first of these is distributed to the middle lobe, and the main tube then passes downwards and backwards into the inferior lobe, giving off in its course a series of large ventral and small dorsal branches. The ventral and dorsal branches arise alternately, and there are usually four of each. The branch to the middle lobe is regarded as the first of the ventral series.

The *left* bronchus passes below the level of the pulmonary artery before it divides, and hence all its branches are *hyparterial*; it may therefore be looked upon as equivalent to that portion of the right bronchus which lies on the distal side of its *eparterial* branch. The first branch of the left bronchus arises about 5 cm. from the bifurcation of the trachea, and is distributed to the superior lobe. The main stem then enters the inferior lobe, where it divides into ventral and dorsal branches similar to those in the right lung. The branch to the superior lobe of the left lung is regarded as the first of the ventral series.

Structure.—The lungs are composed of a serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The *serous coat* is the pulmonary pleura (p. 1081); it is thin, transparent, and invests the entire organ as far as the root.

The *subserous areolar tissue* contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inwards between the lobules.

The *parenchyma* is composed of lobules which, although closely connected together by interlobular areolar tissue, are quite distinct from one another, and in the *fetus* may be teased asunder without much difficulty. The lobules vary in size; those on the surface are large, of pyramidal form, the bases turned towards the surface; those in the interior smaller, and of various forms. Each lobule is composed of a lobular bronchiole and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves; all of these structures being connected together by areolar tissue.

The *intrapulmonary bronchi* divide and subdivide throughout the entire organ, the smallest subdivisions constituting the *lobular bronchioles*. The *larger divisions* consist of: (1) an outer coat of fibrous tissue in which are found at intervals irregular plates of hyaline cartilage, most developed at the points of division; (2) internal to the fibrous coat, a layer of circularly disposed smooth muscular fibres, the *bronchial muscle*; and (3) most internally, the *mucous membrane*, lined by columnar ciliated epithelium resting on a basement membrane. The mucous membrane contains numerous elastic fibres running longitudinally, and a certain amount of lymphoid tissue; it is traversed by the

FIG. 960.—A section of the lung of a cat, showing the termination of a bronchus. $\times 50$.

ducts of mucous glands, the acini of which lie in the fibrous coat. The *lobular bronchioles* are about 0.2 mm. in diameter; they differ from the larger tubes in containing no cartilage and in the fact that the ciliated epithelial cells are cubical in shape.

Each bronchiole ends by opening into a wider space known as the *vestibule*, the point of junction of the two being marked by a circular thickening of the bronchial muscle, and by a transition from the ciliated epithelium of the bronchiole to a layer of flattened non-ciliated cells. The vestibule divides into from three to six passages called *atria*. These are lined by flattened non-ciliated epithelium. From each atrium arise two or more *infundibula*, elongated passages, lined by simple squamous epithelium and beset on all sides by hemispherical alveoli or air-cells (fig. 960).

The *alveoli* are lined by a layer of simple squamous epithelium, the cells of which are united at their edges by cement substance. Between the squamous cells are here and there smaller, polygonal, nucleated cells. Outside the epithelial lining is a little delicate connective tissue, containing numerous elastic fibres and a close network of blood-capillaries, and forming a common wall to adjacent alveoli (fig. 961).

The *fetal lung* resembles a gland in that the alveoli have a small lumen and are lined by cubical epithelium (fig. 962). After the first respiration the alveoli become distended, and the epithelium takes on the characters described above.

Vessels and Nerves.—The *pulmonary artery* conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes and end in a dense capillary network in the walls of the infundibula and alveoli. The arteries of neighbouring lobules are independent of one another.

The *pulmonary capillaries* form plexuses which lie immediately beneath the lining epithelium, in the walls and septa of the alveoli and of the infundibula. In the septa

between the alveoli the capillary network forms a single layer, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin.

The *pulmonary veins* arise from the pulmonary capillaries, the radicles coalescing into larger branches which run through the substance of the lung, independently of the pulmonary arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the lung, the artery usually being above, and the vein below, the bronchus. Finally they open into the left atrium of the heart, conveying oxygenated blood to be distributed to all parts of the body by the aorta.

The *bronchial arteries* supply blood for the nutrition of the lung; they are derived from the thoracic aorta or from the upper aortic intercostal arteries, and, accompanying the bronchial tubes, are distributed to the bronchial glands and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form, in the muscular coat, a capillary plexus from which branches are given off to form a second plexus in the mucous coat; this plexus communicates with branches of the pulmonary artery, and empties itself into the pulmonary veins. Others are distributed

FIG. 961.—A section of the lung of a kitten. Silver preparation. $\times 350$.

in the interlobular areolar tissue, and end partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung, beneath the pleura, where they form a capillary network.

The *bronchial veins*, usually two on either side, are formed at the root of the lung, and receive superficial and deep veins corresponding with branches of the bronchial arteries; they do not, however, receive all the blood conveyed by the arteries, as some of it passes into the pulmonary veins. The right bronchial veins end in the azygos vein, the left bronchial veins in the left superior intercostal vein or the accessory hemiazygos vein.

The *lymphatics* of the lungs are described on p. 738.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and vagus. The filaments from these plexuses accompany the bronchial tubes, supplying efferent fibres to the bronchial muscle and afferent fibres to the bronchial mucous membrane and to the alveoli of the lung. Small ganglia are found upon these nerves.

Applied Anatomy.—The lungs may be wounded or torn in three ways: (1) by compression of the chest, without any injury to the ribs; (2) by a fractured rib penetrating the lung; (3) by stabs, gunshot wounds, etc.

The first form, where the lung is ruptured by external compression, without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung, i.e. the most fixed part, and thus, implicating the great vessels, is frequently fatal. It would seem *a priori* a most unusual injury, and its exact mode of causation is difficult to interpret.

In the second variety, when the wound in the lung is produced by the penetration of a broken rib, both the costal pleura and pulmonary pleura must necessarily be injured, and consequently the air taken into the wounded alveoli may find its way through these wounds into the cellular tissue of the parietes of the chest, producing *surgical emphysema*. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air passes straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes therefore the most important

sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries of the third variety—that is to say, from external wounds, from stabs, gunshot injuries, and such like—in which case air passes either from the wound of the lung or from the external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air is drawn into the wound during inspiration, and then forced into the cellular tissue during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the chest no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This takes place where the wound is large, and constitutes one form of *hernia* of the lung. Another form of *hernia* of the lung occurs, though very rarely, after wounds of the chest-wall, when the wound has healed and the cicatrix subsequently

FIG. 962.—A section of the lung of a pig-embryo, 13 cm. long, showing the glandular character of the developing alveoli. $\times 70$. (J. M. Flint.)

yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls in during inspiration, and disappears on holding the breath.

An incision into the lung is occasionally required in cases of abscess the result of pneumonia or the presence of a foreign body, and from an abscess in the liver which has made its way through the Diaphragm into the lung substance, and also in cases of hydatid disease. In these cases there is always risk of hæmorrhage, and it has been recommended that the lung tissue should be penetrated by the actual cautery rather than with the knife. Unless adhesions have formed between the two layers of the pleura, the pleural cavity must necessarily be opened, and there is the further risk of pneumothorax, and possibly of septic infection. It is therefore advisable to suture the lung to the opening in the thoracic wall, and wait for adhesions to form before perforating the lung.

The routine methods of physical examination—inspection, palpation, percussion, and auscultation—are nowhere more important than they are in the diagnosis of disease of the lungs. It is essential, too, that in every case the two sides of the chest should be compared with one another, and that the wide variations that may be met with under normal conditions in different persons and at different ages should be kept in mind when the chest is being examined. On inspection the thorax will be seen to be enlarged and

barrel-shaped in emphysema, in which the volume of the lungs is increased by dilatation of their alveoli, or in an acute attack of asthma, or when a large pleural effusion or mediastinal tumour is present. The chest-wall will be flattened or sunken, on the other hand, over an area of lung that has collapsed or become fibrosed, as often happens in chronic pulmonary tuberculosis. The respiratory movements of the chest-wall will be lessened, or even absent, over a part or the whole of the affected side in such acute disorders as pleurisy, pneumonia, or pleural effusion, or in more chronic disease where the underlying lung is fibrosed, or is crushed to one side by a mediastinal tumour; and by the use of the x-rays a corresponding loss of movement or displacement of the Diaphragm on the affected side can often be observed. Under normal conditions the intercostal spaces are a little depressed; but when a large effusion or new growth fills up one of the pleural cavities they may be obliterated or even bulging on that side.

On *palpation* the hand can be used to verify the eye's impressions as to the degree of movement, on respiration, of any part of the chest-wall. The facility with which the vibrations produced by the voice are conducted from the larynx by the underlying lung to the hand (in the form of *vocal fremitus*) can also be tested. The vocal fremitus is commonly much increased over the consolidated area in pneumonia or in fibrosis of the lung, and much diminished over a pleural effusion when the lung is pushed up by the fluid towards the top of the pleural cavity. It is also diminished, but to a less extent, in emphysema, and in bronchitis when the bronchi are blocked by secretion. In bronchitis the bubbling of the secretion in the tubes can often be felt by a hand placed on the chest-wall as the patient breathes; and in chronic pleurisy the friction of the two roughened pleural surfaces against one another can sometimes be felt in the same way. It must be remembered that the vocal fremitus in front and behind is normally greater at the right apex than the left. This is because the apex of the right lung lies in close contact with the trachea (see fig. 954), while the apex of the left lung is separated from it by the œsophagus and other structures.

On *percussion*, the normal resonance of the pulmonary tissue is found to be increased in emphysema, and in pneumothorax (p. 1034) this hyper-resonance may be still further increased. The resonance is lessened in any condition causing collapse or solidification of the lung-tissue, or when its place is taken by fluid (pleural effusion) or some solid growth (mediastinal tumour). Thus dullness on percussion at the bases of the lungs is common in the hypostatic congestion of the bases seen in heart-failure; dullness at the right base is often due to compression of the lung by enlargement of the liver; some dullness at the apex of a lung is frequently met with in tuberculosis of that part, before the disease has progressed very far. Complete dullness over one side of the chest, back and front alike, except at the apex, is common when a large pleural effusion has taken the lung's place. Von Korányi, Grocco, and others have drawn attention to a triangular patch of dullness along the vertebral column (the paravertebral triangle of dullness) on the unaffected side in pleural effusion; this triangle of dullness is said to be absent in other conditions causing loss of pulmonary resonance on percussion, and is due to shifting over of the contents of the posterior mediastinal cavity towards the sound side. The apex of this triangle is in the middle line at the upper level of the fluid effusion; its base, some 5 cm. to 10 cm. in length, runs horizontally outwards from the middle line at the level where the pulmonary resonance normally comes to an end.

On *auscultation* of the lungs, both in health and disease, the variety of sounds to be heard is very great. It is impossible to give adequate consideration to them here, and for further information reference should be made to the text-books dealing with the subject.*

DIGESTIVE APPARATUS

The apparatus for the digestion of the food consists of the digestive tube and of certain accessory organs.

The **digestive tube**, about 9 metres long, extends from the mouth to the anus, and is lined throughout by mucous membrane. It consists of the following parts: at its commencement is the *mouth*, where provision is made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the organs of deglutition, the *pharynx* and the *œsophagus*, which convey the food into the *stomach*, where the first stages of the digestive process take place; the stomach is followed by the *small intestine*, which consists of three parts, the *duodenum*, the *jejunum*, and *ileum*. In the small intestine the process of digestion is completed and the resulting products are absorbed into the blood and lacteal vessels. Finally the small intestine ends in the *large intestine*, which is made up of the *cæcum*, the *colon*, the *rectum*, and the *anal canal*, the last terminating on the surface of the body at the *anus*.

* See especially *Auscultation and Percussion*, by Samuel Gee. Edit. 5, 1906. Smith, Elder & Co.

The **accessory organs** are the *teeth*, for purposes of mastication; the three pairs of *salivary glands*—the *parotid*, *submaxillary*, and *sublingual*—the secretion from which mixes with the food in the mouth and acts chemically on one of its constituents; the *liver* and the *pancreas*, two large glands in the abdomen, the secretions of which, in addition to that of numerous minute glands in the walls of the alimentary canal, take part in the process of digestion.

THE MOUTH CAVITY (CAVUM ORIS)

The **cavity of the mouth** is placed at the commencement of the digestive tube (fig. 963); it consists of an outer, smaller portion, the *vestibule*, and an inner, larger part, the *mouth cavity proper*.

The *vestibule of the mouth* is a slit-like space, bounded externally by the lips and cheeks; internally by the gums and teeth. It communicates with the surface of the body by the *rima* or *orifice of the mouth*. Above and below, it is limited by the reflection of the mucous membrane from the lips and cheeks to the gums covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid salivary glands, and communicates, when the jaws are closed, with the mouth cavity proper by an aperture on either side behind, the wisdom teeth, and by narrow clefts between opposing teeth.

The *mouth cavity proper* (fig. 984) is bounded laterally and in front by the alveolar arches with their contained teeth; behind, it communicates with the pharynx by a constricted aperture termed the *isthmus faucium*. Its roof consists of the hard and soft palates, while the greater part of the floor is formed by the tongue, the remainder by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner surface of the mandible. It receives the secretion from the submaxillary and sublingual salivary glands.

The *mucous membrane* lining the mouth is continuous with the skin at the free margins of the lips, and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it overlies the hard parts bounding the cavity. It is covered by stratified squamous epithelium.

The *lymphatics* of the mouth are described on p. 717.

The **lips** (*labia oris*), the two fleshy folds which surround the rima or orifice of the mouth, are formed externally of skin and internally of mucous membrane, between which are found the Orbicularis oris muscle, the labial vessels, some nerves, areolar tissue, and fat, and numerous small labial glands. On the middle part of the outer surface of the upper lip is a shallow vertical groove named the *philtrum* which ends below in a slight prominence and is limited on either side by a ridge. The inner surface of each lip is connected in the middle line to the corresponding gum by a fold of mucous membrane, the *frenulum*—that of the upper lip being the larger.

The *labial glands* are situated between the mucous membrane and the Orbicularis oris, round the orifice of the mouth. They are circular in form, and about the size of small peas; their ducts open upon the mucous membrane. In structure they resemble the salivary glands.

The **cheeks** (*buccæ*) form the sides of the face, and are continuous in front with the lips. They are composed externally of skin, and internally of mucous membrane; between these are a muscular stratum, and a large quantity of fat, together with areolar tissue, vessels, nerves, and buccal glands.

The *mucous membrane* lining the cheek is reflected above and below upon the gums, and is continuous behind with the lining membrane of the soft palate. Opposite the second upper molar tooth is a papilla, on the summit of which the parotid duct opens. The principal muscle of the cheek is the Buccinator; but others enter into its formation, viz. the Zygomaticus, Bisorius, and Platysma.

The *buccal glands* are placed between the mucous membrane and the Buccinator muscle; their structure is similar to that of the labial glands. Four or five, larger than the rest, and placed between the Masseter and Buccinator muscles around the distal extremity of the parotid duct, are called *molar glands*; their ducts open in the mouth opposite the last molar tooth.

The *lymphatics* of the cheeks and lips are described on p. 716.

The gums (gingivæ) are composed of dense fibrous tissue, closely connected to the periosteum of the alveolar processes, and surrounding the necks of the teeth. The gums are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this

FIG. 988.—A sagittal section of the nose, mouth, pharynx, and larynx.

membrane presents numerous fine papillæ, and is reflected into the alveoli, where it is continuous with the periosteal membrane lining these cavities.

Applied Anatomy.—The gums are occasionally the seat of considerable hypertrophy, forming a lobulated vascular fold growing up in front of and behind the teeth, so as almost to bury them. They may also become swollen and congested, bleeding freely, and often becoming ulcerated. The condition is known as *spongy gums*, and may occur in scurvy, leucæmia, and dyspepsia, in ill-fed tuberculous children, and from the administration of mercury; the gums are very tender, mastication is painful, and there is often considerable labor. The dental margin of the gum presents a finely stippled blue or blue-black

line in cases of *lead poisoning*, due to the local deposit of black lead sulphide. In cases of *bismuth poisoning*, such as may occur after the too generous use of insoluble bismuth salts in the surgical treatment of gunshot wounds, a very similar but more diffuse black line due to the local deposit of black sulphide of bismuth may appear, together with patches of minute black dots about other parts of the mucous membrane of the mouth. The collection of tartar, which consists of the secretion from the gums mixed with fragments of food and salivary salts, may give rise to a condition known as *pyorrhœa alveolaris*, which is an inflammatory condition of the gums, followed by the gradual absorption of the alveolus and the falling out of the teeth. Fibrous tumours (epulis), myeloid growths, and epitheliomata are met with in the gums.

The **palate** forms the roof of the mouth: it consists of two portions, the hard palate in front, the soft palate behind.

The **hard palate** (fig. 971) is formed by the palatine processes of the maxillæ and the horizontal parts of the palatine bones; it is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered by a dense tissue, formed by the periosteum and mucous membrane, which are intimately connected. Along the middle line is a linear raphe, which ends anteriorly in a small papilla corresponding with the incisive canal. On either side and in front of the raphe the mucous membrane is thick, pale in colour, and corrugated; behind, it is thin, smooth, and of a deeper colour: it is covered with stratified squamous epithelium, and furnished with numerous palatine glands which lie between the mucous membrane and the periosteum.

The **soft palate** (fig. 984) is a movable fold, suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position (i.e. relaxed and pendent) its anterior surface is concave, and marked by a median raphe. Its posterior surface is convex, and continuous with the floor of the nasal cavities. Its superior border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its inferior border is free. The lower portion of the soft palate hangs like a curtain between the mouth and the pharynx, and is termed the *palatine velum*.

Hanging from the middle of its lower border is a small, conical, pendulous process, the *palatine uvula*; and arching lateralwards and downwards from the base of the uvula on either side are two curved folds of mucous membrane, containing muscular fibres, called the *arches* or *pillars of the fauces* (p. 1072).

The *mucous membrane of the soft palate* is thin, and covered with stratified squamous epithelium, excepting near the pharyngeal ostium of the auditory tube, where it is columnar and ciliated. Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and round the uvula.

Vessels and Nerves.—The *arteries* supplying the palate are the ascending palatine branch of the external maxillary artery, the descending palatine branch of the internal maxillary artery, and the palatine branch of the ascending pharyngeal artery. The *veins* end chiefly in the pterygoid and tonsillar plexuses. The *lymphatic vessels* pass to the deep cervical lymph-glands. The *sensory nerves* are derived from the palatine, nasopalatine and glossopharyngeal nerves.

Applied Anatomy.—The occurrence of a congenital cleft in the palate has been already referred to as a defect in development (p. 264). After the operation for the closure of a cleft in the palate, the palatine muscles, especially the Tensor and Levator veli palatini, have a tendency to retard the healing process by active traction upon the line of suture. To obviate this, it is necessary to divide them. This is best done by making longitudinal incisions, on either side, parallel to the cleft and just medial to the pterygoid hamulus, in such a position as to avoid the descending palatine artery. Acquired perforations of the palate are almost invariably the result of the breaking down of syphilitic gummata. The ensuing ulceration may continue until practically the whole palate, both hard and soft, has been destroyed. Tumours of the palate, both innocent and malignant, are occasionally seen.

Paralysis of the soft palate often occurs after diphtheria. It gives rise to a change in the voice, which becomes nasal, and to the regurgitation of fluids down the nose when their swallowing is attempted. On inspection, the palate is seen to hang flaccid and motionless when phonation or deglutition is attempted; it is also anæsthetic.

THE SALIVARY GLANDS (fig. 966)

Three pairs of salivary glands communicate with the mouth, and pour their secretion into its cavity: they are the parotid, submaxillary, and sublingual.

Parotid gland.—The parotid gland (figs. 964, 965), the largest of the three, has an average weight of about 25 gm. It lies upon the side of the face, immediately below and in front of the external ear. The main portion of the gland is superficial, somewhat flattened and quadrilateral in form, and is placed between the ramus of the mandible in front and the mastoid process and Sternocleidomastoideus behind, overlapping, however, both boundaries. Above, it is broad and reaches nearly to the zygomatic arch; below, it tapers

FIG. 964.—The right parotid gland. Posterior and deep aspects.

somewhat to about the level of a line joining the tip of the mastoid process to the angle of the mandible. The remainder of the gland is irregularly wedge-shaped and extends deeply inwards towards the pharyngeal wall.

The gland is enclosed within a capsule continuous with the fascia colli (deep cervical fascia); the part covering the superficial surface is dense, closely adherent to the gland, and attached to the zygomatic arch; a portion of the fascia, attached to the styloid process and the angle of the mandible, is thickened to form the stylomandibular ligament which intervenes between the parotid and submaxillary glands.

The *anterior surface* of the gland is grooved, being moulded on the posterior border of the ramus of the mandible, and on the posterior borders of the Pterygoideus internus and Masseter. The inner lip of the groove dips, for a short distance, between the two Pterygoid muscles; the outer lip extends for some distance over the superficial surface of the Masseter, and a small portion of it immediately below the zygomatic arch is usually detached, and is named the *accessory part* of the gland.

The *posterior surface* is grooved longitudinally and abuts against the external acoustic meatus, the mastoid process, and the anterior border of the Sternocleidomastoideus.

The *superficial surface*, slightly lobulated, is covered by the skin, the superficial fascia containing the facial branches of the great auricular nerve and some small lymph-glands, and by the fascia which forms the capsule of the gland.

The *deep surface* extends inwards by means of two processes, one of which lies on the Digastricus, styloid process, and the styloid group of muscles, and projects under the mastoid process and Sternocleidomastoideus; the other is situated in front of the styloid process, and sometimes passes into the posterior part of the mandibular fossa behind the temporomandibular joint. The deep surface is in contact with the internal and external carotid arteries, the internal jugular vein, and the vagus and glossopharyngeal nerves.

The gland is separated from the pharyngeal wall by some loose connective tissue.

Structures within the gland.—The external carotid artery lies at first on the deep surface, and then in the substance of the gland. The artery gives off its posterior auricular branch which emerges from the gland behind; the artery then divides into the internal maxillary and superficial temporal arteries; the former runs forwards deep to the neck of the mandible; the latter runs

FIG. 965.—The right parotid gland. Deep and anterior aspects.

upwards across the zygomatic arch and gives off its transverse facial branch which emerges from the front of the gland. Superficial to the arteries are the superficial temporal and internal maxillary veins, uniting to form the posterior facial vein; in the lower part of the gland this vein splits into anterior and posterior divisions. The anterior division emerges from the gland and unites with the anterior facial vein to form the common facial vein; the posterior unites in the gland with the posterior auricular vein to form the external jugular vein. On a still more superficial plane is the facial nerve, the branches of which emerge from the borders of the gland. Branches of the great auricular nerve pierce the gland to join the facial nerve, and the cutaneous part of the auriculotemporal nerve issues from the upper part of the gland.

The parotid duct (Stensen's duct) (fig. 966) is about 5 cm. long. It begins by numerous branches from the anterior part of the gland, crosses the Masseter, and at the anterior border of this muscle turns inwards nearly at a right angle, passes through the corpus adiposum of the cheek and pierces the Buccinator; it then runs for a short distance obliquely forwards between the Buccinator and mucous membrane of the mouth, and opens upon a small papilla on the oral surface of the cheek opposite the second upper molar tooth. While crossing the Masseter it receives the duct of the accessory portion; in this position it lies between the branches of the facial nerve; the accessory part of the gland and the transverse facial artery are above it.

Structure.—The wall of the parotid duct is of considerable thickness, and consists of a thick external fibrous coat which contains unstriated muscular fibres, and an internal mucous coat which is lined with short columnar epithelium. Its canal is about the size of a crow-quill, but at its orifice on the oral surface of the cheek its lumen is greatly reduced in size.

Vessels and Nerves.—The *arteries* supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near the gland. The *veins* empty themselves into the external jugular, through some of its tributaries. The *lymphatics* end in the superficial and deep cervical lymph-glands, passing in their course through two or three lymph-glands, on the surface and in the substance of the parotid. The *nerves* are derived from the facial, auriculotemporal and great auricular nerves and from the plexus of the sympathetic on the external carotid artery. It is probable that the branch from the auriculotemporal nerve is derived from the glossopharyngeal through the otic ganglion; at all events, in some of the lower animals this has been proved experimentally to be the case.

Submaxillary gland.—The submaxillary gland (fig. 966) is irregular in form and about the size of a walnut. A considerable part of it is situated in the

FIG. 966.—A dissection showing the salivary glands of the right side.

submaxillary triangle, reaching forwards to the anterior belly of the Digastricus and backwards to the stylomandibular ligament, which intervenes between it and the parotid gland. Above, it extends under cover of the body of the mandible; below, it usually overlaps the intermediate tendon of the Digastricus and the insertion of the Stylohyoideus, while from its deep surface a tongue-like *deep process* extends forwards above the Mylohyoideus muscle.

Its *superficial surface* consists of an upper and a lower part. The *upper part* is directed outwards, and lies partly against the submaxillary depression on the inner surface of the body of the mandible, and partly on the Pterygoideus internus. The *lower part* is directed downwards and outwards, and is covered by the skin, superficial fascia, Platysma, and deep cervical fascia; it is crossed by the anterior facial vein and by filaments of the facial nerve; in contact with it, near the mandible, are the submaxillary lymph-glands.

The *deep surface* is in relation with the Mylohyoideus, Hyoglossus, Styloglossus, Stylohyoideus, and posterior belly of the Digastricus; in contact with it are the mylohyoid nerve and the mylohyoid and submental vessels.

The external maxillary artery is imbedded in a groove in the posterior border of the gland.

The *deep process* of the gland extends forwards as far as the posterior end of the sublingual gland, and lies between the Mylohyoideus below and externally and the Hyoglossus and Styloglossus internally; above it are the lingual nerve and submaxillary ganglion; below it, the hypoglossal nerve and its vena comitans.

The submaxillary duct (Wharton's duct) is about 5 cm. long, and its wall is much thinner than that of the parotid duct. It begins by numerous branches from the deep surface of the gland, and runs forwards between the Mylohyoideus and the Hyoglossus, and then between the sublingual gland and the Genioglossus, and opens by a narrow orifice on the summit of a small papilla, at the side of the frenulum linguæ. On the Hyoglossus it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it is crossed laterally by the lingual nerve; the terminal branches of the lingual nerve ascend on its medial side.

Vessels and Nerves.—The *arteries* supplying the submaxillary gland are branches of the external maxillary and lingual arteries. Its *veins* follow the course of the arteries. The *nerves* are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial nerve, the lingual branch of the mandibular nerve and the sympathetic.

FIG. 967.—Section of the submaxillary gland of a kitten. Duct semidiagrammatic. $\times 200$.

In the dog and cat the submaxillary gland receives its nerve-supply through Langley's ganglion (p. 1053).

Sublingual gland.—The sublingual gland (fig. 966) is the smallest of the three glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frenulum linguæ, in contact with the sublingual depression on the inner surface of the mandible, close to the symphysis. It is narrow, flattened, shaped somewhat like an almond, and weighs between 3 and 4 gms. It is in relation, *above*, with the mucous membrane; *below*, with the Mylohyoideus; *in front*, with its fellow of the opposite side; *behind*, with the deep part of the submaxillary gland; *later-*

ally, with the mandible; and *medially*, with the Genioglossus, from which it is separated by the lingual nerve and the submaxillary duct. Its excretory ducts are from eight to twenty in number. Of the *smaller sublingual ducts* (ducts of Rivinus), some join the submaxillary duct; others open separately into the mouth, on the elevated crest of mucous membrane (*plica sublingualis*), caused by the projection of the gland, on either side of the frenulum linguæ. One or more join to form the *larger sublingual duct* (duct of Bartholin), which opens with or near to the submaxillary duct.

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual and chorda tympani nerves, and from the sympathetic.

In the dog and cat the sublingual gland receives its nerve-supply through the submaxillary ganglion.

Structure of the salivary glands.—The salivary glands are compound racemose glands, consisting of numerous lobes, which are made up of lobules, connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of

a single duct, the branches ending in dilated ends or alveoli on which the capillaries are distributed. The alveoli are enclosed by a basement membrane, which is continuous with the membrana propria of the duct and consists of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ in the size and appearance of their secreting cells, and in the nature of their secretion. (1) The mucous variety secretes a viscid fluid, which contains mucin; (2) the serous variety secretes a thinner and more watery fluid. The sublingual gland consists of mucous, and the parotid gland of serous, alveoli. The submaxillary gland contains both mucous and serous alveoli (fig. 969).

The cells in the *mucous alveoli* are columnar in shape (fig. 967). In the fresh condition they contain large granules of mucinogen. In hardened preparations a delicate protoplasmic network is seen, and the cells are clear and transparent. The nucleus is usually situated near the basement membrane, and is flattened.

In some alveoli peculiar crescentic bodies are seen between the cells and the membrana propria. They are termed the *crescents of Gianuzzi*, or the *demilunes of Heidenhain* (fig. 967), and are composed of polyhedral granular cells. Fine canaliculi pass between the mucus-secreting cells to reach the demilunes and even penetrate the cells forming these structures.

In the *serous alveoli* the cells almost completely fill the cavity in the resting condition of the gland, so that there is hardly any lumen perceptible: they contain secretory granules imbedded in a closely reticulated protoplasm (fig. 968). The cells are more cubical than those of the mucous type; the nucleus of each is spherical and placed near the centre of the cell, and the granules are smaller.

Both mucous and serous cells vary in appearance according to whether the gland is in a resting condition or has been recently active. In the former case the cells are large and contain many secretory granules; in the latter case the cells are shrunken and contain few granules, chiefly collected at the inner ends of the cells. The granules are best seen in fresh preparations.

The ducts are lined at their origins by epithelium which differs little from the pavement form. As the ducts enlarge, the epithelial cells change to the columnar type, and the part of the cell next the basement membrane is finely striated.

The lobules of the salivary glands are richly supplied with blood-vessels, which form a dense network in the intervalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue. The

nerve-fibrils pierce the basement membrane of the alveoli, and end in branched varicose filaments between the secreting cells. In the hilum of the submaxillary gland there is a collection of nerve-cells termed *Langley's ganglion*.

Accessory glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. Some of these occur in the tongue (p. 1070); others lie around and in the palatine tonsil between its crypts, and large numbers are present in the soft palate, the lips and cheeks. These glands are of the same structure as the larger salivary glands, and are of the mucous or mixed type.

FIG. 968.—Section of the parotid gland of a cat. $\times 200$.

FIG. 969.—A section of a human submaxillary gland. (R. Heidenhain.)

To the right of the figure is a group of mucous alveoli, to the left a group of serous alveoli.

Applied Anatomy.—The parotid glands, and much less often the other salivary glands, are liable to an acute infectious inflammation, known in the case of the parotid as *mumps*. The affected glands swell up, becoming tense, tender, and painful; much pain is felt when swallowing or mastication is attempted, and salivation may or may not occur. The inflammation goes down after a few days; suppuration in the affected glands is very rare.

THE TEETH (DENTES) (figs. 970 to 972)

Man is provided with two sets of teeth, which make their appearance at different periods of life. Those of the first set are temporary and appear during the first and second years; they are called the *deciduous* or *milk* teeth.

FIG. 970.—A side view of the teeth and jaws.

Those of the second set begin to replace the deciduous set about the sixth year; they are all established by the twenty-fifth year, and, since they may continue until old age, are named the *permanent* teeth.

The *deciduous teeth* are twenty in number: four incisors, two canines, and four molars in each jaw.

The *permanent teeth* are thirty-two in number: four incisors, two canines, four premolars, and six molars in each jaw.

The dental formulæ may be represented as follows:

Deciduous Teeth.

	mol.	can.	in.	in.	can.	mol.	
Upper jaw	2	1	2	2	1	2	Total 20
Lower jaw	2	1	2	2	1	2	

Permanent Teeth.

	mol.	premol.	can.	in.	in.	can.	premol.	mol.	
Upper jaw	3	2	1	2	2	1	2	3	Total 32
Lower jaw	3	2	1	2	2	1	2	3	

General characteristics.—Each tooth consists of three portions: the *crown*, projecting beyond the gum; the *root*, imbedded in the alveolus; and the *neck*, the constricted portion between the crown and the root.

The roots of the teeth are firmly implanted in the alveoli of the maxilla and mandible. Each alveolus is lined by periosteum which invests the tooth as far as its neck, and is continuous above with the fibrous tissue of the gums.

In consequence of the curve of the dental arch, terms such as anterior and posterior, if applied to the teeth, would be misleading and confusing. Special terms are therefore used to indicate the different surfaces of a tooth: the surface directed towards the lips or cheek is known as the *labial* or *buccal* surface; that directed towards the tongue is described as the *lingual* surface; those surfaces which touch neighbouring teeth are termed *surfaces of contact*. In the

FIG. 971.—The permanent teeth of the upper dental arch. Seen from below.

case of the incisor and canine teeth the surfaces of contact are medial and lateral; in the premolar and molar teeth they are anterior and posterior.

The superior dental arch is larger than the inferior, so that in the normal condition the teeth of the maxilla slightly overlap those of the mandible both in front and at the sides. Since the upper central incisors are wider than the lower, the other teeth in the upper arch are thrown somewhat distalwards, and the two sets do not quite correspond to each other when the mouth is closed. Thus the upper canine tooth rests partly on the lower canine and partly on the first premolar, and the cusps of the upper molar teeth lie behind the corresponding cusps of the lower molar teeth. The dental arches, however, end at nearly the same points behind because the upper molars, especially the third molars, are smaller than the lower.

PERMANENT TEETH (figs. 970 to 973)

The incisive teeth, or incisors, are so named because they present sharp cutting edges, adapted for biting the food. They are eight in number, and form the four front teeth in each dental arch.

The *crown* of each is directed vertically, and is chisel-shaped, being bevelled so as to present a sharp horizontal cutting edge, which, before being subjected

FIG. 972.—The permanent teeth of the right half of the lower dental arch. From above.

to attrition, presents three small prominent points separated by two notches. It is convex on its labial surface; concave on its lingual surface, where, in the teeth of the upper arch, it is frequently marked by an inverted V-shaped eminence, situated near the gum. This is known as the *basal ridge* or *cingulum*. The *neck* is constricted. The *root* is long, single, conical, transversely flattened, thicker in front than behind, and slightly grooved on either side in the longitudinal direction.

The *upper incisors* are larger and stronger than the lower, and are directed obliquely downwards and forwards. They overlap the lower incisors and their free edges are consequently bevelled at the expense of their lingual surfaces. Their roots are conical and nearly cylindrical. The central upper incisors are larger than the lateral.

The *lower incisors* are smaller than the upper. They are placed vertically and are somewhat bevelled in front, where they have been worn down by contact with the overlapping edges of the upper teeth. Their roots are flattened at the sides. The central lower incisors are smaller than the lateral, and are the least of all the incisors.

The *canine teeth* (cuspid) are four in number, two in the upper, and two in the lower arch, one being placed lateral to each

lateral incisor. They are larger and stronger than the incisors, and their roots sink deeply into the bones and cause well-marked prominences upon their surfaces.

FIG. 973.—Permanent teeth. Right side. (Burchard.)

The *crown* of each is large and conical, very convex on its labial surface, a little hollowed and uneven on its lingual surface, and tapering to a blunted point or cusp, which projects beyond the level of the other teeth. The *root*

is single, but longer and thicker than that of the incisors; it is conical in form, compressed laterally, and marked by a slight groove on either side.

The *upper canine teeth* (popularly called *eye-teeth*) are larger and longer than the lower, and usually present a distinct basal ridge.

The *lower canine teeth* are placed nearer the middle line than the upper so that their summits correspond to the intervals between the upper canines and the lateral incisors. The roots of the lower canines are occasionally double.

The *premolars* or *bicuspid teeth* are eight in number, four in each arch. They are situated laterally to and behind the canine teeth, and are smaller and shorter than these.

The *crown* of each is compressed from before backwards, and surmounted by two pyramidal eminences or cusps, a labial and a lingual, separated by a groove. Of the two cusps the labial is the larger and more prominent. The *neck* is oval. The *root* is generally single, but presents in front and behind a deep groove, which indicates a tendency in the root to become double.

The *upper premolars* are larger, and show a greater tendency to the division of their roots than the lower; this is especially the case in the first upper premolar. The roots of the *lower premolars* are nearly cylindrical.

The *molar teeth* are the largest of the permanent set, and their broad crowns are adapted for grinding the food. They are twelve in number, six in each arch, three being placed posterior to each of the second premolars.

The *crown* of each is nearly cubical in form, convex on its buccal and lingual surfaces, flattened on its surfaces of contact; it is surmounted by four or five tubercles, or cusps, separated from each other by a crucial depression; hence the molars are sometimes termed *multicuspids*. The *neck* is distinct, large, and rounded.

Upper molars.—As a rule the first of the upper molars is the largest, and the third the smallest. The crown of the first has usually four tubercles; that of the second, three or four; that of the third, three. Each upper molar has three roots, and of these two are buccal, and nearly parallel to one another; the third is lingual and diverges from the others as it runs upwards. The roots of the third molar (*dens serotinus* or *wisdom-tooth*) are more or less fused together.

Lower molars.—The lower molars are larger than the upper. On the crown of the first there are usually five tubercles; on the crowns of the second and third, four or five. Each lower molar has two roots, an anterior and a posterior, which are curved backwards; both roots are grooved longitudinally, indicating a tendency to division. The two roots of the third molar (*dens serotinus* or *wisdom-tooth*) are more or less united.

FIG. 974.—The deciduous teeth.
Left side.

DECIDUOUS TEETH (fig. 974)

The deciduous or milk teeth resemble in form the teeth which bear the same names in the permanent set; they are, however, smaller and their necks are more constricted. The second molar is the largest of the deciduous teeth. The first upper molar has three cusps, the second has four. The first lower molar has four cusps; the second has five. The roots of the deciduous molars are smaller than those of the permanent molars; they are also more divergent, owing to the fact that the crowns of the permanent molars are lodged between them.

STRUCTURE OF THE TEETH

On making a vertical section of a tooth (fig. 975), a cavity is seen in the crown and in the centre of each root; it opens by a minute orifice at the extremity of the latter. This is called the *pulp cavity*, and contains the *dental pulp*, a loose connective tissue richly supplied with vessels and nerves which enter the cavity through the small aperture at the point of each root. Some of the cells of the pulp are arranged as a layer on the wall

of the pulp cavity; they are named *odontoblasts*, and during the development of the tooth are columnar in shape, but after the dentine is fully formed they become flattened. Each sends a fine process into a canaliculus in the dentine.

The solid portion of the tooth consists of (1) the *ivory* or *dentine*, which forms the bulk of the tooth; (2) the *enamel*, which covers the exposed part of the crown; and (3) a thin layer of bone, the *cement* or *crusta petrosa*, which is disposed on the surface of the root.

The *dentine* (*substantia eburnea*) (fig. 978) is a modification of osseous tissue, from which it differs, however, in structure. On microscopic examination it is seen to consist

FIG. 975.—A vertical section of a tooth *in situ*.
×15.

[c is placed in the pulp cavity, opposite the neck of the tooth; the part above it is the crown, that below is the root. 1. Enamel with radial and concentric markings 2. Dentine with tubules and incremental lines. 3. Cement or crusta petrosa, with bone-cells. 4. Dental perlosteum. 5. Mandible.

FIG. 977.—A vertical section of a premolar tooth. (Magnified.)

of a number of minute wavy and branching tubes, the *dental canaliculi*, imbedded in a dense homogeneous substance, the *matrix*.

The *dental canaliculi* (fig. 978) are placed parallel with one another, and open at their inner ends into the pulp cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. These canaliculi vary in direction: thus in a tooth of the mandible they are vertical in the upper portion of the crown, becoming oblique and then horizontal in the neck and upper part of the root, while towards the lower part of the root they are inclined downwards. In their course they divide and subdivide dichotomously, and, especially in the root, give off minute branches, which join together in loops in the matrix, or end blindly. Near the periphery of the dentine, the finer ramifications of the canaliculi terminate imperceptibly by free ends. The dental canaliculi have definite walls, consisting of an elastic homogeneous membrane, the *dentinal sheath of Neumann*, which resists the action of acids; they contain slender

cylindrical prolongations of the odontoblasts, first described by Tomes, and named *Tomes' fibres* or *dentinal fibres*.

The *matrix* is translucent, and contains the chief part of the earthy matter of the dentine. In it are a number of fine fibrils, which are continuous with the fibrils of the dental pulp. After the earthy matter has been removed by steeping a tooth in weak acid, the animal basis remaining may be torn into laminae which run parallel with the pulp cavity, across the direction of the tubes. These layers may be indicated in a section of dry dentine by a series of somewhat parallel lines—the *contour lines of Owen*—composed of imperfectly calcified dentine. In consequence of the imperfection in the calcifying process, little irregular cavities are left, termed *interglobular spaces* (fig. 978). A series of these spaces is found towards the outer surface of the dentine, where they form a layer which is sometimes known as the *granular layer of Tomes*. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the *lines of Schreger*, and are due to the optical effect of simultaneous curvature of the dentinal fibres.

Chemical composition.—According to Berzelius and von Bibra, dentine consists of 28 parts of animal and 72 parts of earthy matter. The animal matter is converted by boiling into gelatin. The earthy matter consists of phosphate, carbonate, and a trace of fluoride of calcium, phosphate of magnesium, and other salts; over 80 per cent. of the earthy matter consists of calcium phosphate.

The **enamel** (*substantia adamantina*) is the hardest and most compact part of the tooth, and forms a thin crust over the exposed part of the crown, as far as the commencement of the root. It is thickest on the grinding surface of the crown, until worn away by attrition, and becomes thinner towards the neck. The cement may overlap, or be overlapped by, the enamel, but in the majority the cement and enamel meet without overlapping. Sections usually show a series of brown lines which form acute angles with the contour of the underlying dentine. The enamel consists of minute rods or columns termed *enamel fibres* or *prisms* (*prismata adamantina*). They lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and forming the free surface of the crown by the other extremity. The columns are directed vertically on the summit of the crown, horizontally at the sides; they are about 4μ in diameter, and pursue a more or less wavy course. Each column is a six-sided prism and presents numerous dark transverse shadings; these shadings are probably due to the manner in which the columns are developed in successive stages, producing shallow constrictions, as will be subsequently explained.

Numerous minute interstices intervene between the enamel fibres near their dentinal ends, a provision calculated to allow of the permeation of fluids from the dental canaliculi into the substance of the enamel.

Chemical composition.—Enamel consists of from 98 to 99 per cent. of earthy matter, and from 1 to 2 per cent. of animal matter. The earthy matter consists of phosphate of lime, with traces of fluoride and carbonate of calcium, phosphate of magnesium, and other salts. According to Tomes there is no animal matter in properly calcified enamel.

The **crusta petrosa** or **cement** (*substantia ossea*) is disposed as a thin layer on the roots of the teeth, from the termination of the enamel to the apex of each root, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunae and canaliculi which characterise true bone; the canaliculi of adjacent lacunae intercommunicate as in ordinary bone; and those more deeply placed join with the adjacent dental canaliculi. Normal cement is non-vascular.

As age advances, the cement increases in thickness, and gives rise to those bony growths or exostoses so common in the teeth of the aged: the pulp cavity also becomes partially filled up by a hard substance, intermediate in structure between dentine and bone (*secondary* or *adventitious dentine*, Tomes). It appears to be formed by a slow conversion of the dental pulp, which shrinks, or even disappears.

FIG. 978.—Transverse section of a portion of the root of a canine tooth. $\times 300$.

DEVELOPMENT OF THE TEETH (figs. 979 to 982)

In describing the development of the teeth, the mode of formation of the deciduous teeth must first be considered, and then that of the permanent series.

Development of the deciduous teeth.—The development of the deciduous teeth begins about the sixth week of foetal life as a thickening of the epithelium along the line of the future jaw, the thickening being due to a rapid multiplication of the more deeply situated epithelial cells. As the cells multiply they extend into the subjacent mesoderm, and thus form a ridge or strand of cells imbedded in mesoderm. About the seventh week a longitudinal splitting or cleavage of this strand of cells takes place, and it becomes divided into two strands; the separation begins in front and extends laterally, the process occupying four or five weeks. Of the two strands thus formed, the labial forms the *labio-dental lamina*; while the other, the lingual, is the ridge of cells in connexion with which the teeth, both deciduous and permanent, are developed. Hence it is known as the *dental lamina* or *common dental germ*. It forms a flat band of cells, which grows into the substance of the embryonic jaw, at first horizontally inwards, and then, as the teeth develop, vertically, i.e. upwards in the upper jaw, and downwards in the lower jaw. While still maintaining a horizontal direction it has two edges—an *attached edge*, con-

tinuous with the epithelium lining the mouth, and a *free edge*, projecting inwards, and imbedded in the mesodermal tissue of the embryonic jaw. Along its line of attachment to the buccal epithelium is a shallow groove, the *dental furrow*.

About the ninth week the dental lamina begins to develop enlargements along its free border. These are ten in number in each jaw, and each corresponds with a future deciduous tooth. They consist of masses of epithelial cells; and the cells of the deeper part—that is, the part farthest from the margin of the jaw—increase rapidly and spread out in all directions. Each mass thus comes to assume a club shape, connected with the general epithelial lining of the mouth by a narrow neck, embraced by mesoderm. They are now known as *special dental germs*. After a time the lower expanded portion inclines outwards, so as to form an angle with the superficial constricted portion, which is sometimes known as the *neck* of the special dental germ. About the tenth week the mesodermal tissue beneath these special dental germs becomes differentiated into papillæ; these grow upwards, and come in contact with the epithelial cells of the special dental germs, which become folded over them like a hood or cap. There is, then, at this stage a papilla (or papillæ) which has already begun to assume somewhat the shape of the crown of the future tooth, and from which the dentine and pulp of the tooth are formed, surmounted by a dome or cap of epithelial cells from which the enamel is derived.

In the meantime, while these changes have been going on, the dental lamina has been extending backwards behind the special dental germ corresponding with the second deciduous molar tooth, and at about the seventeenth week of foetal life it presents an enlargement, the special dental germ for the first permanent molar, soon followed by the formation of a papilla in the mesodermal tissue for the same tooth. This is followed, about the fourth month after birth, by a further extension backwards of the dental lamina, with the formation of another enlargement and its corresponding papilla for the second molar. And finally the process is repeated for the third molar, its papilla appearing about the fifth year of life.

After the formation of the special dental germs, the dental lamina undergoes atrophic changes and becomes cribriform, except on the lingual aspect of each of the special germs of the temporary teeth, where it undergoes a local thickening forming the special dental germ of each of the successional permanent teeth—i.e. the ten anterior ones in each jaw. Here the same process goes on as has been described in connexion with those of the deciduous teeth: that is, they recede into the substance of the gum behind the germs of the deciduous teeth. As they recede they become club-shaped, form expansions at their distal extremities, and finally meet papillæ which have been formed in the mesoderm, just in the same manner as was the case in the deciduous teeth. The apex of each papilla indents the dental germ which encloses it, and, forming a cap for it, becomes converted into the enamel, while the papilla forms the dentine and pulp of the permanent tooth.

The special dental germs consist at first of rounded or polyhedral epithelial cells. After the formation of the papillæ, these cells undergo a differentiation into three layers. Those which are in immediate contact with the papilla become elongated, and form a layer of well-marked columnar epithelium coating the papilla. They are the cells which form the enamel fibres, and are therefore termed *enamel cells* or *ameloblasts*. The cells of the outer layer of the special dental germ, which are in contact with the inner surface of the dental sac, presently to be described, are much shorter, cubical in form, and are

FIG. 980.—A sagittal section through the canine tooth of an embryo 40 mm. long. $\times 100$. (Röse.)

L.F. Labiodental furrow. The other lettering as in fig. 979.

named the *external enamel epithelium*. All the intermediate round cells of the dental germ between these two layers undergo a peculiar change. They become stellate in shape and develop processes, which unite to form a network into which fluid is secreted; this has the appearance of a jelly, and to it the names of *enamel pulp* or *stellate reticulum* are given. Between the stellate reticulum and the layer of ameloblasts there is a *stratum intermedium* consisting of two or three layers of round or polygonal cells. This transformed special dental germ is now known under the name of *enamel organ* (fig. 981).

While these changes are going on, a sac is formed around each enamel organ from the surrounding mesodermal tissue. This is known as the *dental sac*, and is a vascular membrane of connective tissue. It grows up from below, and thus encloses the whole tooth germ; as it grows it causes the neck of the enamel organ to atrophy and disappear; so that all communication between the enamel organ and the superficial epithelium is cut off. At this stage there are vascular papillæ surmounted by caps of epithelial cells, the whole being surrounded by membranous sacs.

Formation of the enamel.—The enamel is formed exclusively from the enamel cells or ameloblasts of the special dental germ, either by direct calcification of the columnar cells, which become elongated into the hexagonal rods of the enamel, or, as is more generally believed, as a secretion from the ameloblasts, within which calcareous matter is subsequently deposited.

The process begins at the apex of each cusp, at the ends of the enamel cells in contact with the dental papilla. Here a fine globular deposit takes place, being apparently shed from the end of the ameloblasts. It is known by the name of the *enamel droplet*, and resembles keratin in its resistance to the action of mineral acids. This droplet then becomes fibrous and calcifies, and forms the first layer of the enamel; a second droplet now appears and calcifies, and so on; successive droplets of keratin-like material are shed from the ameloblasts and form successive layers of enamel, the ameloblasts gradually receding as each layer is produced, until at the termination of the process they have

almost disappeared. The enamel pulp and stratum intermedium atrophy and disappear, so that the newly formed calcified material and the external enamel epithelium come into apposition. The crown of the tooth is covered for a time by a distinct membrane. This is known as the *cuticula dentis*, or *Nasmyth's membrane*, and is believed to be formed by the external epithelium of the enamel-organ. It forms a horny layer, which may be separated from the subjacent calcified mass by the action of strong acids. It is marked by the hexagonal impressions of the enamel prisms, and, when stained by nitrate of silver, shows the characteristic lines of interepithelial cement.

Formation of the dentine.—While these changes are taking place in the epithelium to form the enamel, contemporaneous changes occurring in the differentiated mesoderm of the dental papillæ result in the formation of the dentine. As before stated, the first germs of the dentine are the papillæ, corresponding in number with the teeth, formed from the soft mesodermal tissue which bounds the depressions containing the special enamel germs. The papillæ grow upwards into the enamel germs and become covered by them, both being enclosed in a vascular connective tissue, the dental sac, in the manner above described. Each papilla then consists of rounded cells, and is very vascular, and soon begins to assume the shape of the future tooth. The next step is the appearance of the *odontoblasts*, which have a relation to the development of the teeth similar to that of the osteoblasts to the formation of bone. They are formed from the cells of the periphery of the

FIG. 981.—A vertical section of the mandible of an early human fœtus. $\times 25$.

papilla—that is to say, from the cells in immediate contact with the ameloblasts of the special dental germ. These cells become elongated, one end of the elongated cell resting against the epithelium of the special dental germs, the other being tapered and often branched. By the direct transformation of the peripheral ends of these cells, or by a secretion from them, a layer of uncalcified matrix (*prodentine*) is formed which caps the cusp, or cusps if there be more than one, of the papillæ. This matrix becomes fibrillated, and in it islets of calcification make their appearance, and, coalescing, give rise to a continuous layer of calcified material which covers each cusp and constitutes the first layer of dentine. The odontoblasts retire towards the centre of the papilla, and, as they do so, produce successive layers of dentine from their peripheral extremities—that is to say, they form the dental matrix in which calcification subsequently takes place. As they thus recede from the periphery of the papilla, they leave behind them filamentous processes of cell protoplasm, provided with finer side processes; these are surrounded by calcified material, and thus form the dental canaliculi, and, by their side branches, the anastomosing canaliculi; the processes of protoplasm contained within these constitute the dentinal fibres (Tomes' fibres). In this way the entire thickness of the dentine is developed, the wall of each canaliculus being completed throughout its whole length by a single odontoblast. The central part of the papilla does not undergo calcification, but persists as the pulp of the tooth. In certain places uncalcified portions of the matrix remain between the successive layers of dentine, and give rise to the interglobular spaces alluded to above.

Formation of the cement.—The root of the tooth begins to be formed shortly before the crown emerges through the gum, but is not completed until some time afterwards. Its form is determined by a downgrowth of the epithelium of the dental germ, which extends

below the region where the enamel is to be formed, almost as far as the situation of the apex of the future root (fig. 982). This fold of epithelium is known as the *epithelial sheath*, and on its papillary surface odontoblasts appear, which in turn form dentine, so that the dentine formation is identical in the crown and root of the tooth. The vascular tissues of the dental sac then break through the epithelial sheath, and spread over the surface of the root as a layer of bone-forming material. In this layer osteoblasts make their appearance, and the process of ossification goes on in identically the same manner as in the ordinary intramembranous ossification of bone. The remains of the epithelial sheath may sometimes be seen in the adult as isolated groups of cells in the alveolodental periosteum.

Formation of the alveoli.—About the fourteenth week of embryonic life the dental lamina becomes enclosed in a trough or groove of mesodermal tissue, which at first is common to all the dental germs, but subsequently becomes divided by bony septa into loculi, each locus containing the special dental germ of a deciduous tooth and its corresponding permanent tooth. After birth each cavity becomes subdivided, so as to form separate loculi (the future alveoli) for the deciduous tooth and its corresponding permanent tooth. Although at one time the whole of the growing tooth is contained in the cavity of the alveolus, the latter never completely encloses it, since there is always an aperture over the top of the crown filled by soft tissue, by which the dental sac is connected with the surface of the gum, and which in the permanent teeth is called the *gubernaculum dentis*.

Development of the permanent teeth.—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the deciduous teeth, and which, like them, are ten in number in each jaw; these are the *successional permanent teeth*; and (2) those which have no deciduous predecessors, but are superadded distal to the temporary dental series. These are three in number on either side in each jaw, and are termed *superadded permanent teeth*. They are the three molars of the permanent set, the molars of the deciduous set being replaced by the premolars of the permanent set. The development of the successional permanent teeth—the ten anterior ones in either jaw—has already been indicated. During their development the permanent teeth, enclosed in their sacs, come to be placed on the lingual side of the deciduous teeth and more distant from the margin of the future gum, and, as already stated, are separated from them by bony partitions. As the crown of the permanent tooth grows, absorption of these bony partitions and of the root of the deciduous tooth takes place, through the agency of *osteoclasts* which appear at this time, and finally nothing but the crown of the deciduous tooth remains. This is shed or removed, and the permanent tooth takes its place.

The superadded permanent teeth are developed in the manner already described, by extensions backward of the posterior part of the dental lamina in each jaw.

Eruption.—When the calcification of the different tissues of the tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterwards subjected, eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the root. At the same time the septa between the dental sacs ossify, and separate the alveoli; these firmly embrace the necks of the teeth, and afford them a solid basis of support.

The eruption of the deciduous teeth commences about the seventh month after birth, and is completed about the end of the second year, the teeth of the lower jaw preceding those of the upper.

FIG. 982.—A longitudinal section of the lower part of a growing tooth, showing the extension of the layer of ameloblasts beyond the crown to mark off the limit of formation of the dentine of the root. (Rösc.) (From Quain's Elements of Anatomy, Vol. II. Part I.)

ad. Ameloblasts, continuous below with the epithelial sheath. d. Dentine. en. Enamel. od. Odontoblasts. p. Pulp.

The following, according to C. S. Tomes, are the most usual times of eruption of the deciduous teeth :

Lower central incisors	6 to 9 months
Upper incisors	8 to 10 months
Lower lateral incisors and first molars	15 to 21 months
Canines	16 to 20 months
Second molars	20 to 24 months

There are, however, considerable variations in these times. According to Holt : a child at the age of one year should have six teeth ; at the age of a year and a half, twelve teeth ; at the age of two years, sixteen teeth ; and at the age of two and a half years, twenty teeth.

Calcification of the permanent teeth proceeds in the following order in the lower jaw (in the upper jaw it takes place a little later) : the first molar, soon after birth ; the central and lateral incisors, and the canine, about six months after birth ; the premolars, at the second year, or a little later ; the second molar, about the end of the second year ; the third molar, about the twelfth year.

The eruption of the permanent teeth takes place at the following periods, the teeth of the lower jaw preceding those of the upper by short intervals :

First molars	6th year
Two central incisors	7th year
Two lateral incisors	8th year
First premolars	9th year
Second premolars	10th year
Canines	11th to 12th year
Second molars	12th to 13th year
Third molars	17th to 25th year

Towards the sixth year, before any of the deciduous teeth are shed, there are twenty-four teeth in each jaw, viz. the ten deciduous teeth and the crowns of all the permanent teeth except the third molars.

Applied Anatomy.—As a consequence of local irritation or of chronic digestive disturbances occurring during their eruption, both the deciduous and the permanent teeth may show defective development or irregular transverse furrowing and erosions ; this is particularly the case with the incisors. Quite distinct from, and much less common than this, is a characteristic malformation of the two upper central permanent incisors seen in patients with inherited syphilis, and first described by Hutchinson. Here there is a crescentic notch in the anterior surface and at the cutting edge of the tooth, which is pug-shaped, stunted, and set obliquely in the gum, pointing either medialwards or lateralwards. Numerous forms of innocent *tumour* arising from the teeth, or from their constituent layers, have been described under the general name of *odontoma*. Infection of the pulp of a tooth by bacteria gaining access thereto in consequence of dental caries gives rise to the common and very painful *alveolar abscess* ; starting in the apical space between the root of the tooth and its alveolar socket, the pus from such an abscess may make its way into the maxillary antrum, or burst through the hard palate or cheek. A more superficial abscess forming between the root of a tooth and the gum is known as a *gum-boil*.

THE TONGUE (LINGUA)

The tongue is the principal organ of the sense of taste, and an important organ of speech ; it also assists in the mastication and deglutition of the food. It is situated in the floor of the mouth, within the curve of the body of the mandible.

Its *root* (fig. 942) is connected with the hyoid bone by the Hyoglossi and Genioglossi muscles and the hyoglossal membrane ; with the epiglottis by three *glosso-epiglottic* folds of mucous membrane ; with the soft palate by the glossopalatine arches ; and with the pharynx by the Constrictores pharyngis superiores and the mucous membrane. Its *apex*, thin and narrow, is directed forwards against the lingual surfaces of the lower incisor teeth. Its *inferior surface* (fig. 983) is connected with the mandible by the Genioglossi ; from it the mucous membrane passes across the floor of the mouth to the lingual surface of the gum ; and, in the middle line, is elevated into a vertical fold, the *frenulum lingue*. On either side of the frenulum is a slight fold of the mucous

membrane, the *plica fimbriata*, the free edge of which occasionally exhibits a series of fringe-like processes.

The apex, sides and dorsum, and part of the inferior surface of the tongue are free.

The *dorsum* of the tongue (fig. 984) is convex and divided by a *median sulcus* which ends behind, about 3 cm. from the root of the tongue, in a depression, the *foramen cæcum*; from this foramen a shallow groove, the *sulcus terminalis*, runs lateralwards and forwards on either side to the margin of the tongue. The part in front of this groove, forming about two-thirds of the dorsum, looks upwards, and is rough and covered with papillæ; the posterior third is directed

FIG. 983.—The mouth cavity. The apex of the tongue is turned upwards, and on the right side a superficial dissection of its under surface has been made.

backwards and is smoother; it contains numerous muciparous glands and lymph follicles (*lingual tonsil*). The *foramen cæcum* is the remains of the upper part of the *thyroglossal duct* or diverticulum from which the thyroid gland is developed; the pyramidal lobe of the thyroid gland indicates the position of the lower part of the duct (p. 131).

The *papillæ of the tongue* (fig. 984) are projections of the corium. They are thickly distributed over the anterior two-thirds of the dorsum, giving to this part its characteristic roughness. The papillæ are grouped under the terms *papillæ vallatæ*, *papillæ fungiformes*, *papillæ conicæ*, and *papillæ simplices*.

The *papillæ vallatæ* (fig. 985) are of large size, and vary from eight to twelve in number. They are situated on the dorsum of the tongue, and form a V-shaped row immediately in front of the *sulcus terminalis*. Each papilla is from 1 mm. to 2 mm. in diameter, and is attached to the bottom of a circular depression of the mucous membrane; each depression is surrounded by a wall (*vallum*), and between this and the papilla is a circular sulcus or fossa. The papilla is

shaped like a truncated cone, the smaller end being attached to the tongue; the broader end projects a little above the surface of the tongue, and is studded with numerous small secondary papillæ. The entire papilla and the surrounding fossa and vallum are covered by stratified squamous epithelium.

The *papillæ fungiformes* (fig. 987), more numerous than the preceding, are found chiefly at the sides and apex of the tongue, but are scattered irregularly and sparingly over the dorsum. They are easily distinguished from the papillæ

FIG. 984.—The mouth cavity. The cheeks have been slit transversely and the tongue pulled forwards.

conicæ by their large size, rounded shape, and deep red colour. They are narrow at their attachment to the tongue, but broad and rounded at the free extremities, and covered with secondary papillæ. On the sides of the tongue, where they are somewhat flattened, they are termed *papillæ lenticulares*.

The *papillæ conicæ* (fig. 986) cover the anterior two-thirds of the dorsum. They are very minute, conical or cylindrical in shape, and arranged in lines parallel with the two rows of the papillæ vallatæ, excepting at the apex of the tongue, where their direction is transverse. Like the vallate and fungiform papillæ, the papillæ conicæ present numerous secondary papillæ which are, however, more pointed and contain a larger proportion of elastic fibres. The epithelium covering the papillæ conicæ may be split up into filamentous processes, each of which forms the apex of one of the secondary papillæ; these

processes are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated.

The *papillæ simplices* are similar to those of the skin, and cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely set microscopic elevations of the corium, each containing a capillary loop, covered by a layer of epithelium.

FIG. 986.—A papilla conica. Magnified.

Muscles of the tongue.—The tongue is divided into right and left halves by a median fibrous septum which extends throughout its entire length and is fixed below to the hyoid bone. In either half there are two sets of muscles, extrinsic and intrinsic; the former have their origins outside the tongue, the latter are contained entirely within it.

The *extrinsic muscles* (fig. 988) are :

Genioglossus.
Hyoglossus.

Chondroglossus.
Styloglossus.

Glossopalatinus.*

The **Genioglossus** is a triangular muscle placed close to and parallel with the median plane. It arises by a short tendon from the superior mental spine on the inner surface of the symphysis menti, immediately above the Geniohyoideus, and spreads out in a fan-like form. The inferior fibres are attached by a thin aponeurosis to the upper part of the body of the hyoid bone, a few passing between the Hyoglossus and Chondroglossus to blend with the Constrictores pharyngis; the middle fibres pass backwards, and the superior ones upwards and forwards, to enter the whole length of the under surface of the tongue, from the root to the apex. The muscles of opposite sides are separated posteriorly by the median fibrous septum of the tongue; in front, they are more or less blended owing to the decussation of fasciculi in the median plane.

The **Hyoglossus**, thin and quadrilateral, arises from the front of the lateral part of the body and from the whole length of the greater cornu of the hyoid bone; it passes almost vertically upwards and enters the side of the tongue, between the Styloglossus and Longitudinalis inferior. The fibres arising from the body of the hyoid bone overlap those from the greater cornu.

FIG. 987.—A section of a papilla fungiformis. Magnified.

* The *Glossopalatinus* (Palatoglossus), although one of the muscles of the tongue, is more closely associated with the soft palate both in situation and function; it is consequently described with the muscles of that structure (p. 1075).

Relations.—The Hyoglossus is in relation by its *superficial surface* with the Digastricus, the Stylohyoideus, Styloglossus, and Mylohyoideus, the submaxillary ganglion, the lingual and hypoglossal nerves, the ranine vein, the sublingual gland, the deep portion of the submaxillary gland, and the submaxillary duct. By its *deep surface* it is in relation with the stylohyoid ligament, the Genioglossus, Longitudinalis linguae inferior, and Constrictor pharyngis medius, the lingual vessels, and the glossopharyngeal nerve.

The **Chondroglossus** is sometimes described as a part of the Hyoglossus, but is separated from it by fibres of the Genioglossus which pass to the side of the pharynx. It is about 2 cm. long, and arises from the medial side and base of the lesser cornu and contiguous portion of the body of the hyoid bone; it ascends and blends with the intrinsic muscular fibres of the tongue, between the Hyoglossus and Genioglossus.

FIG. 988.—The extrinsic muscles of the tongue. Left side.

A small slip arises occasionally from the cartilago triticea in the lateral hyothyroid ligament and enters the tongue with the hindermost fibres of the Hyoglossus.

The **Styloglossus**, the shortest and smallest of the three styloid muscles, arises from the anterior and lateral surfaces of the styloid process, near its apex, and from the stylomandibular ligament. Passing downwards and forwards between the internal and external carotid arteries, it divides upon the side of the tongue into two portions; one, longitudinal, enters the side of the tongue near its dorsal surface, blending with the fibres of the Longitudinalis linguae inferior in front of the Hyoglossus; the other, oblique, overlaps the Hyoglossus and decussates with its fibres.

The *intrinsic muscles* (fig. 989) are:

Longitudinalis linguae superior.
Longitudinalis linguae inferior.

Transversus linguae.
Verticalis linguae.

The **Longitudinalis linguae superior** is a thin stratum of oblique and longitudinal fibres immediately underlying the mucous membrane on the

dorsum of the tongue. It arises from the submucous fibrous layer close to the epiglottis, and from the median fibrous septum, and runs forward to the edges of the tongue.

The *Longitudinalis linguae inferior* is a narrow band situated on the under surface of the tongue between the *Genioglossus* and *Hyoglossus*. It extends from the root to the apex of the tongue, some of its posterior fibres being connected with the body of the hyoid bone; in front it blends with the fibres of the *Styloglossus*.

The *Transversus linguae* consists of fibres which arise from the median fibrous septum and pass lateralwards to be inserted into the submucous fibrous tissue at the sides of the tongue.

The *Verticalis linguae* is found only at the borders of the fore part of the tongue. Its fibres extend from the upper to the under surface of the organ.

Applied Anatomy.—The median fibrous septum of the tongue is very complete, so that the anastomosis between the two lingual arteries is not very free. This is a point of considerable importance in connexion with removal of one-half of the tongue for cancer, an operation frequently resorted to when the disease is strictly confined to one side of the organ. If the mucous membrane be divided exactly in the middle line, the tongue can be split into halves, without any appreciable hæmorrhage, and the diseased half can then be removed.

Nerves.—The muscles of the tongue described above are supplied by the hypoglossal nerve.

Actions.—The *Genioglossi* draw the tongue forwards, and protrude the apex from the mouth. The two muscles acting in their entirety draw the tongue downwards, so as to make its superior surface concave from side to side forming a channel along which fluids may pass towards the pharynx, as in sucking. The *Hyoglossi* depress the tongue; the *Styloglossi* draw it upwards and backwards. The *Glossopalatini* raise the root of the tongue. The intrinsic muscles are mainly concerned in altering the shape of the tongue; thus, the *Longitudinales linguae superior* and *inferior* tend to shorten it, but the former, in addition, turns the tip and sides upwards so as to render the dorsum concave, while the latter pulls the tip downwards and renders the dorsum convex. The *Transversus linguae* narrows and elongates the tongue, and the *Verticalis linguae* flattens and broadens it. The complex arrangement of the lingual muscles enables the tongue to assume the forms necessary for the production of the different consonantal sounds; and Macalister * states 'there is reason to believe that the musculature of the tongue varies in different races owing to the hereditary practice and habitual use of certain motions required for enunciating the several vernacular languages.'

Structure of the tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer.

The mucous membrane covering the under surface of the tongue is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane of the dorsum of the tongue behind the sulcus terminalis is thick and freely movable over the subjacent parts. It contains a large number of lymphoid follicles, which together constitute what is sometimes termed the *lingual tonsil*. Each follicle forms a rounded eminence, the centre of which is perforated by a minute orifice leading into a funnel-shaped cavity or recess; around this recess are grouped numerous oval or rounded

FIG. 989.—A coronal section of the tongue, showing the intrinsic muscles. (Altered from Krause.)

nodules of lymphoid tissue, each enveloped by a capsule derived from the submucous fibrous layer, while opening into the bottom of the recesses are also seen the ducts of mucous glands. The mucous membrane on the anterior part of the dorsum of the tongue is thin, intimately adherent to the muscular tissue, and presents numerous minute surface eminences, the *papillæ* of the tongue. It consists of a layer of connective tissue, the *corium* or *mucosa*, covered with epithelium.

The epithelium is of the stratified squamous variety, similar to, but much thinner and less complex than that of the skin; and each papilla has a separate investment from root to summit.

The *corium* consists of a dense felt-work of fibrous connective tissue, with numerous elastic fibres, firmly connected with the fibrous tissue forming the septa between the muscular bundles of the tongue. It contains the ramifications of the numerous vessels and nerves from which the papillæ are supplied, large plexuses of lymphatic vessels, and the glands of the tongue.

Structure of the papillæ.—The papillæ apparently resemble in structure those of the cutis, consisting of cone-shaped projections of connective tissue, covered with a thick layer of stratified squamous epithelium, and containing one or more capillary loops, among which nerves are distributed in great abundance, especially in the vallate and fungiform papillæ. They exhibit secondary papillæ, as already described.

FIG. 990.—A vertical section of a papilla foliata of a rabbit, passing across the folia. (Ranvier.)

a. Serous gland. g. Gustatory calyx. n. Nerve-bundles. p. Central lamina of corium. v. Lateral lamina. v. Section across a sinus-like vein, which traverses the whole length of the folium.

Glands of the tongue.—The tongue is provided with mucous and serous glands.

The *mucous glands* are similar in structure to the labial and buccal glands. They are found especially at the back part behind the vallate papillæ, but are also present at the apex and marginal parts. In this connexion the anterior lingual glands of Blandin or Nuhn require special notice. They are situated on the under surface of the apex of the tongue (fig. 983), one on either side of the frenulum, where they are covered by a fasciculus of muscular fibres derived from the Styloglossus and Longitudinalis inferior. They are from 12 mm. to 25 mm. long, and about 8 mm. broad, and each opens by three or four ducts on the under surface of the apex.

The *serous glands* occur only at the back of the tongue in the neighbourhood of the taste-buds, their ducts opening for the most part into the fossæ of the vallate papillæ. These glands are racemose, the duct of each branching into several minute ducts, which end in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste area (Ebner).

The *septum* consists of a vertical layer of fibrous tissue, extending throughout the entire length of the median plane of the tongue, though not quite reaching the dorsum. It is thicker behind than in front, and occasionally contains a small fibrocartilage, about 6 mm. in length. It is well displayed by making a vertical section across the organ.

The *hyoglossal membrane* is a strong fibrous lamina, which connects the under surface of the root of the tongue to the body of the hyoid bone and gives attachment to the inferior fibres of the Genioglossi.

Taste-buds, the end-organs of the gustatory sense, are scattered over the mucous membrane of the mouth and tongue at irregular intervals. They occur especially in the

sides of the vallate papillæ. In the rabbit there is a localised area at the side of the base of the tongue, the *papilla foliata*, in which they are specially abundant (fig. 990). They are described under the organs of the senses (p. 942).

Vessels and Nerves.—The main artery of the tongue is the lingual branch of the external carotid, but the external maxillary and ascending pharyngeal arteries also give branches to it. The veins open into the internal jugular vein.

The lymphatics of the tongue are described on p. 718.

The sensory nerves of the tongue are: (1) the lingual branch of the mandibular, which is the nerve of ordinary sensibility for the anterior two-thirds of the tongue; (2) the chorda tympani branch of the facial, which runs in the sheath of the lingual, and is generally regarded as the nerve of taste for the anterior two-thirds; this nerve is a continuation of the sensory root of the facial (nervus intermedius); (3) the lingual branch of the glossopharyngeal, which is distributed to the mucous membrane at the base and sides of the tongue, and to the papillæ vallatæ, and is the nerve of taste and of general sensation to this region; (4) the superior laryngeal, which sends some fine branches to the root near the epiglottis.

Applied Anatomy.—The tongue is liable to numerous diseases, and any or all of its tissues—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may undergo morbid changes. It is not often the seat of congenital defects, though a few cases of vertical cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of 'tongue tie,' from shortness of the frenulum.

There is one condition which may be regarded as congenital, the so-called macro-glossia, though sometimes it does not evidence itself until a year or two after birth. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a greatly increased development of the lymphatic tissue throughout the organ. It is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply placed sutures.

Acute inflammation of the tongue is attended by great swelling from infiltration of its connective tissue. This may render the patient incapable of swallowing or speaking, may seriously impede respiration, or may end in suppuration, and the formation of an acute abscess.

In all ages the mucous membrane of the tongue has received much sedulous consideration in disease, and it is certain that the amount and the distribution of the 'fur' with which it may be covered often give valuable help in diagnosis. The fur consists of proliferating or desquamated epithelium, bound up with inspissated mucus, the débris of food, and bacteria of all sorts. The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in the various stages of the disease, to which the terms leucoplakia and psoriasis linguæ have been given. They are usually the result of syphilis.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, tuberculosis, syphilis, and cancer. Of these the cancerous ulcer is the most important and also the most common. The variety is the squamous epithelioma, which soon develops into an ulcer with an indurated edge. It causes great pain, which speedily extends to all parts supplied with sensation by the mandibular nerve, especially to the region of the ear (auriculotemporal nerve).

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the scissors; this is usually known as Whitehead's method; and it will generally be sufficient if half the organ is removed. The mouth is widely opened with a gag, and the tongue transfixed with a silk ligature, by which to hold and make traction on it; it is then split down the median septum, and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genioglossus on the affected side are divided with a pair of curved, blunt-pointed scissors. The tongue can now be pulled well out of the mouth and its base is cut through by a series of short snips until the main artery is reached, this being securely ligatured. In the event of the artery being accidentally injured, hæmorrhage can be at once controlled by passing the forefinger over the tongue till it touches the epiglottis, and then turning it towards the side on which the artery is to be compressed, and pushing it forcibly against the jaw (Heath). If the disease has spread to the glossopalatine arch, the Glossopalatinus must be divided higher up than usual, and in some cases, before division, it can be stripped from the buccopharyngeal aponeurosis together with the tonsil, and removed along with half the tongue.

In cases where the submaxillary lymph-glands are involved, an operation in the neck should be resorted to. Having performed a preliminary tracheotomy, Kocher removes the tongue from the neck by an incision from near the lobule of the auricula, down the anterior border of the Sternocleidomastoideus to the level of the greater cornu of the hyoid bone, then forwards to the body of the hyoid bone, and upwards to near the symphysis menti. The lingual artery is secured, and by a careful dissection the submaxillary lymph-glands and the tongue are removed. If the lymph-glands in the submaxillary

region are in any way affected, an extensive dissection of these will be required if there is any chance of eradicating the disease, and for this purpose it will be found necessary to remove the submaxillary salivary gland.

The more recent operations aim at, first, clearing the neck thoroughly of affected glands, both in the submaxillary region and along the carotid sheath; and, secondly, removal of the tongue from within the mouth, leaving if possible the floor of the mouth intact, so as to avoid soiling the large wound in the neck by the discharges from the mouth.

THE FAUCES (fig. 984)

The aperture by which the mouth communicates with the pharynx is called the *isthmus faucium*. It is bounded, above, by the soft palate; below, by the dorsum of the tongue; and on either side, by the glossopalatine arch.

The *glossopalatine arch* (anterior pillar of the fauces) on either side runs downwards, lateralwards, and forwards from the inferior surface of the soft palate to the side of the tongue, and is formed by the projection of the *Glossopalatinus* with its covering mucous membrane.

The *pharyngopalatine arch* (posterior pillar of the fauces) is larger and projects farther towards the middle line than the glossopalatine; it runs downwards, lateralwards, and backwards from the margin of the uvula to the side of the pharynx, and is formed by the projection of the *Pharyngopalatinus*, covered by mucous membrane. The arches are separated below by a triangular interval, the *sinus tonsillaris*, in which the palatine tonsil is lodged.

The *palatine tonsils* are two masses of lymphoid tissue, situated in the lateral walls of the oral part of the pharynx. Each tonsil occupies the lower part of the triangular interval (*sinus tonsillaris*) between the glossopalatine and pharyngopalatine arches; the upper part of the sinus is known as the *supratonsillar fossa*. A crescentic or triangular fold of mucous membrane, within which is a layer of fibrous tissue continuous with the capsule of the tonsil, passes backwards from the glossopalatine arch. The upper part of this fold, termed the *plica semilunaris*, or *plica supratonsillaris*, stretches between the two arches and forms the medial wall of the supratonsillar fossa; the lower part of the fold, named the *plica triangularis*, forms the medial wall of the anterior and lower parts of the sinus tonsillaris; it overlaps, and is frequently adherent to, the tonsil. The tonsil extends forwards for a variable distance under cover of the *plica triangularis* and the glossopalatine arch, and upwards around the supratonsillar fossa and into the soft palate. A considerable part of the tonsil is therefore below the level of the surrounding mucous membrane (i.e. imbedded), while the remainder projects as the visible tonsil. In the child the tonsils are relatively (and frequently absolutely) larger than in the adult, and about one-third of the tonsil is imbedded (Hett and Butterfield *). After puberty the imbedded portion diminishes considerably in size, and the tonsil assumes a disc-like form, flattened from side to side; the shape and size of the tonsil, however, vary considerably in different individuals.

The *free surface* of the tonsil presents from twelve to fifteen orifices leading into small crypts or recesses from which numerous follicles branch out into the tonsillar substance.

The *lateral or deep surface* is adherent to a fibrous capsule which is continued into the *plica triangularis*. This surface is separated from the Constrictor pharyngis superior by some loose connective tissue; this muscle intervenes between the tonsil and the external maxillary artery with its tonsillar and ascending palatine branches. Some muscular fibres are inserted into the lower and posterior parts of the capsule. The internal carotid artery lies behind and lateral to the tonsil at a distance of about 25 mm. from it.

In the operation of 'enucleation' of the tonsil, advantage is taken of the fact that its deep surface is encapsuled, the entire tonsil and the capsule being removed.

The palatine tonsils form part of a circular band of adenoid tissue which guards the opening into the digestive and respiratory tubes. The anterior part of the ring is formed by the submucous adenoid collections (*lingual tonsil*)

on the posterior part of the tongue; the lateral portions consist of the palatine tonsils and the adenoid collections in the vicinity of the auditory tubes, while the ring is completed behind by the pharyngeal tonsil on the posterior wall of the pharynx. In the intervals between these main masses are smaller collections of adenoid tissue.

FIG. 991.—Vertical section of the tonsil of a dog. $\times 15$.

Structure (fig. 991).—The crypts of the tonsil are lined by stratified squamous epithelium, continuous with that of the mucous membrane of the pharynx. In the recesses the epithelium is closely applied to the lymphoid tissue which forms the substance of the tonsil, and is invaded by numerous lymph-corpuscles. Probably some of the latter pass into the mouth and form the so-called salivary corpuscles. The lymphoid tissue is arranged in nodules or follicles aggregated together. The lymphocytes are less closely packed in the centre of each nodule which is described as a *germ centre*, because multiplication of the corpuscles goes on in this situation. Mucous glands are found subjacent to the tonsil; their ducts open into the tonsillar crypts. Surrounding each follicle is a close plexus of lymphatics, from which the lymphatic vessels pass to the deep cervical lymph-glands in the neighbourhood of the greater cornu of the hyoid bone, behind and below the angle of the mandible (p. 717).

Vessels and Nerves.—The *arteries* supplying the tonsil are the dorsalis linguae from the lingual, the ascending palatine and tonsillar from the external maxillary, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal.

The *veins* end in the tonsillar plexus, on the lateral side of the tonsil.

The *nerves* are derived from the sphenopalatine ganglion, and from the glossopharyngeal nerve.

Applied Anatomy.—The palatine tonsils can be easily inspected by instructing the patient to throw the head back and open his mouth widely; the tongue at the same time being depressed by a spatula or tongue-depressor. The normal tonsil should not project beyond the plane of the glossopalatine arch. They are prone to become enlarged, especially in tuberculous children; and when much increased in size they cause great trouble, owing to obstruction to respiration and deglutition. The tonsils may be the seat of acute inflammation, which may run on to suppuration, requiring evacuation of the pus. The incision into the tonsil should always be made from in front backwards and medialwards. Another form of acute inflammation of the tonsil is follicular tonsillitis, due to the lodgment of micro-organisms in the crypts of the tonsil. The removal of an enlarged tonsil is, as a rule, a very simple operation, and is not usually attended with much hæmorrhage, unless the patient is suffering from hæmophilia. The tonsil may be the seat of malignant growth, either an epithelioma or a lymphosarcoma.

Palatine aponeurosis.—Attached to the posterior border of the hard palate is a thin, firm fibrous lamella which supports the muscles and gives strength to the soft palate. It is thicker above than below, where it becomes very thin and difficult to define. Laterally it is continuous with the tendon of the Tensor veli palatini.

Blakeway* maintains that the palatine aponeurosis is not a separate structure, but is actually the expanded tendon of the Tensor veli palatini.

* *Journal of Anatomy and Physiology*, vol. xlviii.

Muscles of the palate and fauces (fig. 992):

Levator veli palatini.
Tensor veli palatini.
Musculus uvulæ.

Glossopalatinus.
Pharyngopalatinus.

The **Levator veli palatini** (*Levator palati*) is a thick, rounded muscle situated laterally to the choana. It arises from the under surface of the petrous part of the temporal bone, immediately in front of the lower opening of the

FIG. 992.—Dissection of the muscles of the palate from behind.

carotid canal, and from the medial lamina of the cartilage of the auditory tube. After passing above the upper concave margin of the Constrictor pharyngis superior, and in front of the Salpingopharyngeus, it spreads out in the palatine velum, its fibres extending obliquely downwards and medialwards to the middle line, where they blend with those of the opposite side.

The **Tensor veli palatini** (*Tensor palati*) is a broad, thin, muscle placed laterally to the Levator veli palatini. It arises by a flat lamella from the scaphoid fossa at the base of the medial pterygoid lamina, from the medial surface of the spina angularis of the sphenoid, and from the lateral lamina of the cartilage of the auditory tube. Descending vertically between the medial pterygoid lamina and the Pterygoideus internus, it ends in a tendon which winds round the pterygoid hamulus, being retained in this situation by some

of the fibres of origin of the *Pterygoideus internus*. Between the tendon and the hamulus is a small bursa. The tendon then passes medialwards, and is inserted into the palatine aponeurosis and into the surface behind the transverse ridge on the horizontal part of the palatine bone.

The *Musculus uvulæ* (*Azygos uvulæ*) arises from the posterior nasal spine of the palatine bones and from the palatine aponeurosis; it descends to be inserted into the uvula.

The *Glossopalatinus* (*Palatoglossus*) is a small fleshy fasciculus, narrower in the middle than at either end, forming, with the mucous membrane covering its surface, the glossopalatine arch. It arises from the anterior surface of the soft palate, where it is continuous with the muscle of the opposite side, and passing downwards, forwards, and lateralwards in front of the palatine tonsil, is inserted into the side of the tongue, some of its fibres spreading over the dorsum, and others passing deeply into the substance of the organ to intermingle with the *Transversus linguae*.

The *Pharyngopalatinus* (*Palatopharyngeus*) is a long, fleshy fasciculus narrower in the middle than at either side, forming, with the mucous membrane covering its surface, the pharyngopalatine arch. It is separated from the *Glossopalatinus* by an angular interval, in which the palatine tonsil is lodged. It arises from the soft palate, where it is divided into two fasciculi by the *Levator veli palatini* and *Musculus uvulæ*. The *posterior fasciculus* lies in contact with the mucous membrane, and joins with that of the opposite muscle in the middle line; the *anterior fasciculus*, the thicker, lies in the soft palate between the *Levator* and *Tensor*, and joins in the middle line the corresponding part of the opposite muscle. Passing lateralwards and downwards behind the palatine tonsil, the *Pharyngopalatinus* joins the *Stylopharyngeus*, and is inserted with that muscle into the posterior border of the thyroid cartilage, some of its fibres ending on the side of the pharynx, and others passing across the middle line posteriorly, to decussate with the muscle of the opposite side.

In a dissection of the soft palate from its posterior or pharyngeal surface to its anterior or oral surface, the muscles would be exposed in the following order, viz. the posterior fasciculus of the *Pharyngopalatinus*, covered by a continuation of the mucous membrane of the floor of the nasal cavities; the *Musculus uvulæ*; the *Levator veli palatini*; the anterior fasciculus of the *Pharyngopalatinus*; the aponeurosis of the *Tensor veli palatini*; and the *Glossopalatinus*, covered by a continuation of the oral mucous membrane.

Nerves.—The *Tensor veli palatini* is supplied by a branch from the otic ganglion; the remaining muscles of this group are in all probability supplied by the accessory nerve through the pharyngeal plexus.*

Actions.—During the *first stage* of deglutition, the bolus of food is driven back into the fauces by the pressure of the tongue against the hard palate, the base of the tongue being, at the same time, retracted, and the larynx raised, with the pharynx. During the second stage the entrance to the larynx is closed by the drawing forward of the arytaenoid cartilages towards the cushion of the epiglottis—a movement produced by the contraction of the *Thyroarytaenoidei*, the *Arytaenoidei*, and the *Arytaenoepiglottidei*.

After leaving the tongue the bolus passes on to the posterior or laryngeal surface of the epiglottis, and glides along this for a certain distance; then the *Glossopalatini*, the constrictors of the fauces, contract behind it; the palatine velum is slightly raised by the *Levator veli palatini*, and made tense by the *Tensor veli palatini*; and the *Pharyngopalatini*, by their contraction, pull the pharynx upwards over the bolus, and come nearly together, the uvula filling up the slight interval between them. By these means the food is prevented from passing into the nasal part of the pharynx; at the same time, the *Pharyngopalatini* form an inclined plane, directed obliquely downwards and backwards, along the under surface of which the bolus descends into the lower part of the pharynx. The *Salpingopharyngei* raise the upper and lateral parts of the pharynx, i.e. those parts which are above the points where the *Stylopharyngei* are attached to the pharynx.

* The innervation of the soft palate, by Aldren Turner, *Journal of Anatomy and Physiology*, vol. xxiii.

THE PHARYNX

The **pharynx** is the part of the digestive tube which is placed behind the nasal cavities, mouth, and larynx. It is a musculomembranous tube, about 14 cm. long, which extends from the under surface of the skull to the sixth cervical vertebra and the lower border of the cricoid cartilage. Its width varies at different levels; just below the base of the skull, at the level of the pharyngeal recesses or fossæ of Rosenmüller (p. 1077) it is 3·5 cm., while at the lower part of the laryngeal opening, opposite the pyriform sinuses (p. 1077), it is 4·5 cm.; at the junction of the pharynx with the œsophagus it is only about 1·5 cm. It is limited, *above*, by the body of the sphenoid and basilar part of the occipital bone; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column and the prevertebral fascia covering the Longus colli and Longus capitis muscles; *anteriorly*, it is incomplete, and is attached, from above downwards, to the medial pterygoid lamina, pterygomandibular raphe, mandible

FIG. 993.—Front of nasal part of pharynx, as seen with the laryngoscope.

tongue, hyoid bone, and thyreoid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, the glossopharyngeal, vagus, and hypoglossal nerves, and the sympathetic trunks, and above with small parts of the Pterygoidei interni. It communicates with the nasal cavities, the tympanic cavities, the mouth, the larynx, and the œsophagus. The cavity of the pharynx may be subdivided from above downwards into three parts: nasal, oral, and laryngeal (fig. 963).

The **nasal part of the pharynx** (nasopharynx) lies behind the nose and above the level of the soft palate. With the exception of the soft palate its walls are immovable, and consequently its cavity is never obliterated; in this respect it differs from the oral and laryngeal parts. In front (fig. 993) it communicates through the choanæ with the nasal cavities. Behind the lower edge of the soft palate it opens into the oral part of the pharynx. In the act of swallowing this opening is closed by the elevation of the soft palate. On its lateral wall is the *pharyngeal ostium of the auditory tube*, somewhat triangular in shape, and bounded behind by a firm prominence, the *torus* or *cushion*, caused by the medial end of the projecting cartilage of the auditory tube which elevates the mucous membrane. A vertical fold of mucous membrane, the *salpingopharyngeal fold*, stretches from the lower part of the torus to the wall of the pharynx; it contains the Salpingopharyngeus muscle. A second and smaller fold, the *salpingopalatine fold*, stretches from the upper part of the torus to the palate. Behind the torus is a deep recess, the *pharyngeal recess* or

fossa of Rosenmüller. On the posterior wall is a prominence, best marked in childhood, produced by a mass of lymphoid tissue, which is known as the *pharyngeal tonsil*.

The pharyngeal tonsil is visible to the naked eye during the later months of foetal life and usually increases in size up to the age of six or seven years, after which it not infrequently begins to atrophy. In a child of eighteen months it forms a triangular prominence the apex of which is near the nasal septum, and the base at the junction of the roof and posterior wall of the nasal part of the pharynx. The prominence consists of a number of folds which radiate forwards and laterally towards a median recess, the *pharyngeal bursa*. The folds consist mainly of diffuse adenoid tissue, but there are also some deeply placed mucous glands. The pharyngeal bursa lies close to the base of the tonsil and presents the appearance of a blind recess.*

The oral part of the pharynx reaches from the soft palate to the level of the hyoid bone. It opens anteriorly, through the isthmus faucium, into the mouth, while in its lateral wall, between the two palatine arches, is a triangular recess, in which the palatine tonsil is lodged (p. 1072).

The laryngeal part of the pharynx reaches from the hyoid bone to the lower border of the cricoid cartilage, where it is continuous with the oesophagus. In the upper part of its anterior wall is the triangular entrance of the larynx, the base of which is directed forwards and is formed by the epiglottis, while its lateral boundaries are constituted by the aryepiglottic folds. On either side of the laryngeal orifice is a recess, the *sinus piriformis*, bounded medially by the aryepiglottic fold, and laterally by the thyroid cartilage and hyothyroid membrane.

FIG. 994.—The muscles of the pharynx and cheek.

Structure.—The pharynx is composed, from within outwards, of three coats: mucous, fibrous and muscular, the last being covered by the thin buccopharyngeal fascia (p. 486).

The *mucous coat* is continuous with that lining the auditory tubes, the nasal cavities, the mouth, and the larynx. In the nasal part of the pharynx its epithelium is columnar and ciliated; in the oral and laryngeal portions the epithelium is stratified squamous. Between the region covered by ciliated columnar epithelium and that covered by squamous epithelium, there is a narrow intermediate zone where the epithelium is cubical, and the cilia are imperfect or absent. Superiorly, this zone lies near the nasal septum; laterally it passes over the orifice of the auditory tube and inclines backwards at the union of the soft palate with the lateral wall. Beneath the mucous membrane are found racemose mucous glands; they are especially numerous at the upper part of the pharynx around the orifices of the auditory tubes.

The *fibrous coat* is situated between the mucous and muscular layers. It is thick above (pharyngobasilar fascia) where the muscular fibres are wanting, and is firmly connected to the basilar portion of the occipital and the petrous portions of the temporal bones. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band, which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downwards, forming a median raphe, which gives attachment to the Constrictor-pharyngis.

The *muscular coat* consists of the muscles of the pharynx.

* Consult article by J. Synnington, *British Medical Journal*, Oct. 15, 1910.

Muscles of the pharynx.—The muscles of the pharynx (fig. 994) are :

Constrictor pharyngis inferior.
Constrictor pharyngis medius.
Constrictor pharyngis superior.

Stylopharyngeus.
Salpingopharyngeus.
Pharyngopalatinus.*

The **Constrictor pharyngis inferior** is the thickest of the constrictors. It arises from the cricoid cartilage in the interval between the Cricothyroideus in front, and the articular facet for the inferior cornu of the thyroid cartilage behind. It arises from the oblique line on the lamina of the thyroid cartilage, from the surface behind this line nearly as far as the posterior border, and from the inferior cornu. From these origins the fibres spread backwards and medially to be inserted with the muscle of the opposite side into a fibrous raphe in the posterior median line of the pharynx. The inferior fibres are horizontal and continuous with the circular fibres of the œsophagus; the rest ascend, increasing in obliquity, and overlap the Constrictor medius.

Relations.—The Constrictor pharyngis inferior is covered by the buccopharyngeal fascia (p. 436) which surrounds the entire pharynx. *Behind*, the muscle is in relation with the vertebral column and the prevertebral fascia and muscles; *laterally*, with the thyroid gland, the common carotid artery, and the Sternothyroideus; by its *internal surface*, with the Constrictor pharyngis medius, the Stylopharyngeus, the Pharyngopalatinus and the pharyngeal aponeurosis. The internal branch of the superior laryngeal nerve and the laryngeal branch of the superior thyroid artery run near the upper border, and the recurrent nerve and the laryngeal branch of the inferior thyroid artery pass beneath the lower border of this muscle, before they enter the larynx.

The **Constrictor pharyngis medius** is a fan-shaped muscle which arises from the lesser cornu, and from the whole length of the upper border of the greater cornu of the hyoid bone, and from the lower part of the stylohyoid ligament. The fibres diverge from their origin: the lower ones descend beneath the Constrictor inferior, as far as the lower end of the pharynx, the middle fibres pass transversely, and the upper fibres ascend and overlap the Constrictor superior. It is inserted, with the muscle of the opposite side, into the posterior median fibrous raphe.

Relations.—The Constrictor pharyngis medius is separated from the Constrictor pharyngis superior by the glossopharyngeal nerve, the Stylopharyngeus and the stylohyoid ligament; and from the Constrictor pharyngis inferior by the internal branch of the superior laryngeal nerve and laryngeal branch of the superior thyroid artery. *Behind*, it lies on the prevertebral fascia, the Longus colli, and the Longus capitis. *Laterally* it is in relation with the carotid vessels, the pharyngeal plexus, and some lymph-glands. Near its origin it is covered by the Hyoglossus, from which it is separated by the lingual vessels. Its *internal surface* lies upon the Constrictor pharyngis superior, the Stylopharyngeus, the Pharyngopalatinus and the pharyngeal aponeurosis.

The **Constrictor pharyngis superior** is a quadrilateral muscle, thinner and paler than the other two. It arises from the lower third of the posterior margin of the medial pterygoid lamina and its hamulus, from the pterygo-mandibular raphe, from the alveolar process of the mandible above the posterior end of the mylohyoid line, and by a few fibres from the side of the tongue. The fibres curve backwards to be inserted into the median raphe, being also prolonged by means of an aponeurosis to the pharyngeal spine on the basilar part of the occipital bone. The superior fibres arch beneath the Levator veli palatini and the auditory tube. The interval between the upper border of the muscle and the base of the skull is closed by the pharyngobasilar fascia (pharyngeal aponeurosis), and is known as the sinus of Morgagni.

Relations.—The Constrictor pharyngis superior is in relation by its *outer surface* with the prevertebral fascia and muscles, the vertebral column, the internal carotid and ascending pharyngeal arteries, the internal jugular vein and pharyngeal venous plexus, the glossopharyngeal, vagus, hypoglossal and lingual nerves, the sympathetic trunks, the Constrictor pharyngis medius and Pterygoideus internus, the styloid process, the stylohyoid ligament, and the Stylopharyngeus. By its *internal surface* it is in relation with the Pharyngopalatinus, the capsule of the palatine tonsil and the pharyngeal

* The Pharyngopalatinus is described with the muscles of the palate (p. 1075).

aponeurosis. Its lower border is separated from the Constrictor pharyngis medius by the Stylopharyngeus and the glossopharyngeal nerve. In front it is separated from the Buccinator by the pterygomandibular raphe.

The **Stylopharyngeus** (fig. 988) is a long, slender muscle which is cylindrical above and flattened below. It arises from the medial side of the base of the styloid process of the temporal bone, passes downwards along the side of the pharynx between the Constrictor pharyngis superior and the Constrictor pharyngis medius, and spreads out beneath the mucous membrane. Some of its fibres are lost in the constrictor muscles, while others, joining with the Pharyngopalatinus, are inserted into the posterior border of the thyroid cartilage. The glossopharyngeal nerve winds round the lateral side of this muscle to reach the tongue.

The **Salpingopharyngeus** (fig. 992) arises from the inferior part of the cartilage of the auditory tube near its pharyngeal orifice; it passes downwards and blends with the posterior fasciculus of the Pharyngopalatinus.

Nerves.—The Constrictores and the Salpingopharyngeus are supplied by the pharyngeal plexus, and the Stylopharyngeus by the glossopharyngeal nerve. The Constrictor pharyngis inferior receives additional branches from the external laryngeal and recurrent nerves.

Actions.—When deglutition is about to be performed, the pharynx is drawn upwards and dilated in different directions, to receive the food propelled into it from the mouth. The Stylopharyngei, which are much farther removed from one another at their origins than at their insertions, draw the sides of the pharynx upwards and lateralwards, and so increase its transverse diameter; its anteroposterior diameter is increased by the larynx and tongue being carried forwards in their ascent. As soon as the bolus of food is received in the pharynx, the elevator muscles relax, the pharynx descends, and the Constrictores contract upon the bolus, and convey it downwards into the oesophagus.

Applied Anatomy.—Hypertrophy of the lymphoid tissue in the nasal part of the pharynx, commonly known as 'adenoids,' is a frequent cause of mouth-breathing and all its attendant disadvantages and dangers in children. It entails a proneness to inflammation of all parts of the air-passages and of the auditory tubes, and leads to deformed development of the palate and dental arch. In many cases adenoids tend to atrophy about the age of puberty, by which time their presence is likely to have caused permanent injury to the health and development of the patient.

The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments, introduced into the mouth and thrust through the wall of the pharynx. In aneurysm of this vessel in the neck, the tumour necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscles, whereas on the lateral side there are the dense cervical fascia, the muscles descending from the styloid process and the margin of the Sternocleidomastoideus.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, since the numerous recesses are prone to lodge micro-organisms. And, in addition, owing to its exposed situation, the mucous membrane is liable to be irritated by agents introduced during inspiration. The inflammation may be attended with serious consequences: it may extend up the auditory tube and involve the middle ear; it may spread to the entrance of the larynx, causing oedema and seriously interfering with respiration; or, invading the lymphatics, it may spread to the loose areolar tissue surrounding the pharyngeal wall, and may extend far and wide, sometimes into the posterior mediastinal cavity along the oesophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as *retropharyngeal abscess*. This may be due to caries of the cervical vertebrae, or may be caused by suppuration of the lymph-glands, which are situated in this position opposite the epistropheus, and which receive lymphatics from the nasal cavities. In these cases the pus may be easily evacuated by incision with a guarded bistoury, through the mouth, but it is preferable that the abscess should be opened from the neck. In some instances this is perfectly easy: the abscess can be felt bulging at the side of the neck, and merely requires an incision for its relief; but this is not always so, and then an incision should be made along the posterior border of the Sternocleidomastoideus and the deep fascia divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onwards until pus appears in the groove. A pair of sinus forceps is now inserted along the director and the opening into the cavity dilated.

Abscess also occurs in children, underneath the mucous membrane, between it and the pharyngeal aponeurosis. The condition usually arises from a peritonsillar inflammation, which spreads backwards. In some cases an enormous swelling may form, which pushes forwards the soft palate and gives rise to respiratory obstruction. In such cases the abscess should be opened through the mouth with the child in the inverted position, so as

to prevent the first gush of pus from entering the larynx.

Foreign bodies not infrequently become lodged in the pharynx, and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the œsophagus is about 15 cm.

FIG. 995.—The œsophagus.

THE ŒSOPHAGUS (fig. 995).

The œsophagus, or gullet, is a muscular canal, from 23 cm. to 25 cm. long, extending from the pharynx to the stomach. It begins in the neck at the lower border of the cricoid cartilage, opposite the sixth cervical vertebra, where it is continuous with the lower end of the pharynx. It descends along the front of the vertebral column, through the superior and posterior mediastinal cavities, passes through the Diaphragm into the abdomen, and ends at the cardiac orifice of the stomach, opposite the tenth thoracic vertebra. The general direction of the œsophagus is vertical; but it presents two slight curves in its course. At its commencement it is placed in the middle line; but it inclines to the left side as far as the root of the neck, gradually passes again to the middle line, which it reaches at the level of the fifth thoracic vertebra, and again deviates to the left as it passes forwards to the œsophageal hiatus in the Diaphragm. The œsophagus also presents anteroposterior flexures corresponding to the curvatures of the cervical and thoracic portions of the vertebral column. It is the narrowest

part of the digestive tube, and is constricted, (a) at its commencement, (b) where it is crossed by the left bronchus, and (c) where it pierces the Diaphragm.

Relations.—The cervical portion of the œsophagus is in relation, *in front*, with the trachea, and at the lower part of the neck, where it projects to the left side, with the thyroid gland; *behind*, it rests upon the vertebral column and Longus colli muscles; *on either side* it is in relation with the common carotid artery (especially the left), and parts of the lobes of the thyroid gland; the recurrent nerves ascend between it and the trachea; to its left side is the thoracic duct.

The thoracic portion of the œsophagus is at first situated in the superior mediastinal cavity between the trachea and the vertebral column, a little to the left of the median line. It then passes behind and to the right of the aortic arch and descends in the posterior mediastinal cavity, along the right side of the descending aorta, then runs in front and a little to the left of the aorta, and enters the abdomen through the Diaphragm at the level of the tenth thoracic vertebra. It is in relation, *in front*, with the trachea, the left bronchus, the pericardium, and the Diaphragm; *behind*, it rests upon the vertebral column, the Longus colli muscles, the right aortic intercostal arteries, the thoracic duct, and the hemiazygos and accessory hemiazygos veins; and below, near the Diaphragm, upon the front of the aorta. On its *left* side, in the superior mediastinal cavity are the terminal part of the aortic arch, the left subclavian artery, the thoracic duct, and left pleura, while running upwards in the angle between it and the trachea is the left recurrent nerve; below, it is in relation with the descending thoracic aorta. On its *right* side are the right pleura, and the azygos vein which it overlaps. Below the roots of the lungs the vagi descend in close contact with it, the right nerve behind, and the left nerve in front of it; the two nerves unite to form a plexus around the tube.

In the lower part of the posterior mediastinal cavity the thoracic duct lies to the right side of the œsophagus; higher up, it is placed behind it, and crossing about the level of the fourth thoracic vertebra, is continued upwards on its left side.

The abdominal portion of the œsophagus is named the *antrum cardiacum*; it lies in the œsophageal groove on the posterior surface of the left lobe of the liver. It measures about 1.25 cm. in length, and only its front and left aspects are covered by peritoneum. It is conical in shape, and curved sharply to the left, the base of the cone being continuous with the cardiac orifice of the stomach.

Structure (fig. 996).—The œsophagus has four coats: an external or fibrous, a muscular, a submucous or areolar, and an internal or mucous coat.

The *fibrous coat* consists of a layer of areolar tissue, containing many elastic fibres.

The *muscular coat* is composed of two layers of considerable thickness: an external of longitudinal and an internal of circular fibres.

The *longitudinal fibres* form a complete investment for nearly the whole of the œsophagus, but at the upper part of the back of the tube, at a point between 8 cm. and 4 cm. below the cricoid cartilage, they diverge from the middle line and form two longitudinal fasciculi which incline upwards and forwards to the front of the tube. Here they pass beneath the lower border of the Constrictor pharyngis inferior and end in a stout tendon, which is attached to the upper part of the ridge on the posterior surface of the lamina of the cricoid cartilage. The V-shaped interval between the diverging longitudinal fasciculi is filled in by the circular fibres of the œsophagus, thinly covered below by some decussating longitudinal fibres, and above by the overlapping lower edge of the Constrictor pharyngis inferior.

Accessory slips of muscular fibres pass between the œsophagus and the left pleura where the latter covers the thoracic aorta, or the root of the left bronchus, or the back of the pericardium.

FIG. 996.—A section of the human œsophagus. (From a drawing by V. Horsley.) Moderately magnified. (From Quain's Elements of Anatomy, Vol. II. Pt. II.)

The section is transverse and from near the middle of the gullet. *a*. Fibrous covering. *b*. Divided fibres of longitudinal muscular coat. *c*. Transverse muscular fibres. *d*. Submucous or areolar layer. *e*. Muscularis mucosæ. *f*. Mucous membrane, with vessels and part of a lymphoid nodule. *g*. Stratified epithelial lining. *h*. Mucous gland. *i*. Gland duct. *m'*. Striated muscular fibres cut across.

The *circular fibres* are continuous superiorly, on the posterior aspect, with the *Constrictor pharyngis inferior*; anteriorly, the uppermost are inserted into the lateral margins of the tendon of the two longitudinal fasciculi.*

The *muscular fibres* in the upper part of the *œsophagus* are of a red colour, and consist chiefly of the striped variety; but in the lower part they consist for the most part of involuntary fibres.

The *areolar or submucous coat* connects loosely the mucous and muscular coats. It contains the larger blood-vessels and nerves, as well as mucous glands.

The *mucous coat* is thick, of a reddish colour above, and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. It consists of (1) a layer of stratified squamous epithelium, lining the tube, (2) a layer of connective tissue, papillæ from which project into the epithelium, and (3) the *muscularis mucosæ*, a layer of longitudinally arranged non-striped muscular fibres. At the commencement of the *œsophagus* the *muscularis mucosæ* is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The *œsophageal glands* are small compound racemose glands of the mucous type; they are lodged in the submucous tissue, and each opens upon the surface by a long duct.

Vessels and Nerves.—The arteries supplying the *œsophagus* are derived from the inferior thyreoid branch of the thyreocervical trunk, from the descending thoracic aorta, from the left gastric branch of the *cœliac artery*, and from the left inferior phrenic branch of the abdominal aorta. They have for the most part a longitudinal direction.

The nerves are derived from the *vagus nerves* and from the sympathetic trunks; they form a plexus, in which are groups of ganglion-cells, between the two layers of the muscular coat, and a second plexus in the submucous tissue.

Applied Anatomy.—The *œsophagus* may be obstructed by foreign bodies, and also by changes in its coats producing stricture, or by pressure on it from without by new growths or aneurysm, &c. The commoner forms of stricture are: (1) the fibrous, due to cicatrization following destruction of tissue, the result of swallowing boiling or corrosive fluids—here dilatation of the stricture may be carried out; and (2) malignant, usually epitheliomatous in its nature. This may be situated either at the upper end of the tube, opposite the cricoid cartilage, or at its lower end at the cardiac orifice, but is most commonly found in that part of the tube which is crossed by the left bronchus. If, in these cases, the patient is losing weight from insufficient nourishment, the operation of gastrostomy may be performed in order to avoid death from starvation; death, however, most commonly occurs from ulceration of the growth into the mediastinal cavity or air-passages. In cases of non-malignant stricture of the *œsophagus* it may be necessary to dilate the canal by a bougie, when it is of importance that the direction of the *œsophagus* and its relations to surrounding parts should be remembered. In malignant disease of the *œsophagus*, where its tissues have become softened from infiltration of the growth, the passage of a bougie is a very dangerous procedure, as a false passage may easily be made, and the instrument may pass into the mediastinal cavity or into one or other pleural cavity, or even into the pericardium.

In cases of destruction of the *œsophagus*, and consequent symptoms of stricture, produced by an aneurysm of some part of the aorta pressing upon this tube, the passage of a bougie will only hasten the fatal issue, and therefore it is essential that the presence of an aneurysm should be excluded before such an attempt be made in any form of *œsophageal* obstruction.

In passing a bougie the left forefinger should be introduced into the mouth, and the epiglottis felt for, care being taken not to throw the head too far backwards. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently onwards, any force being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the *œsophagus*, and can neither be brought upwards nor moved downwards. When all ordinary means for its removal have failed, open operation by an incision in the neck is the only resource left. This, of course, can only be performed when the foreign body is not very low down. If it is allowed to remain, extensive inflammation and ulceration of the *œsophagus* may ensue, with the development of suppuration and cellulitis in the surrounding tissues.

THE ABDOMEN

The *abdomen* is the largest cavity in the body. The upper extremity is formed by the *Diaphragm*, which extends as a dome over the *abdomen*, so that the cavity extends high into the bony thorax, reaching on the right side, in the mammary line, to the upper border of the fifth rib; on the left side it falls below this level by about 2.5 cm. The lower extremity is formed by

* Abel, *Journal of Anatomy and Physiology*, vol. xlvii.

FIG. 997.—A front view of the thoracic and abdominal viscera.

a. Median plane. b b. Lateral planes. c c. Transtuberular plane. d d. Subcostal plane.
e e. Transpyloric plane.

the structures which clothe the inner surface of the bony pelvis, principally the Levator ani and Coccygeus on either side. These muscles are sometimes termed the *diaphragm of the pelvis*.*

In order to facilitate description the abdomen is artificially divided into two parts: an upper, larger part, the *abdomen proper*; and a lower, smaller part, the *pelvis*. These two parts are continuous with one another through the superior aperture of the lesser pelvis.

The *abdomen proper* differs from the other cavities of the body in being bounded for the most part by muscles and fasciæ, so that it can vary in capacity and shape according to the condition of the viscera which it contains.

It is bounded *in front* and *at the sides* by the abdominal and Iliacus muscles; *behind* by the vertebral column and the Psoas and Quadratus lumborum muscles; *above* by the Diaphragm; *below* by the plane of the superior aperture of the lesser pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surfaces by a layer of fascia.

The Abdomen contains the greater part of the digestive tube; it also contains the liver, pancreas, spleen, kidneys, and suprarenal glands. Most of these structures, as well as the wall of the cavity in which they are contained, are more or less covered by an extensive and complicated serous membrane, the *peritoneum*.

Regions.—For convenience of description of the viscera, as well as of reference to the morbid conditions of the contained parts, the abdomen is divided into nine regions by imaginary planes, two horizontal and two sagittal, passing through the cavity, the edges of the planes being indicated by lines drawn on the surface of the body. Of the horizontal planes the upper or *transpyloric* plane of Addison is indicated by a line encircling the body at the level of a point midway between the jugular notch and the symphysis pubis, the lower by a line carried round the trunk at the level of a point midway between the transpyloric plane and the symphysis pubis. The latter is practically the *intertubercular plane* of Cunningham, who pointed out † that its level corresponds with the prominent and easily defined tubercle on the iliac crest about 5 cm. behind the anterior superior iliac spine. By means of these planes the abdomen is divided into three zones; each of these is further subdivided into three regions by the two sagittal planes, which are indicated on the surface by lines drawn vertically through points halfway between the anterior superior iliac spines and the symphysis pubis.‡

The middle region of the upper zone is the *epigastric*; and the lateral regions, the *right* and *left hypochondriac*. The central region of the middle zone is the *umbilical*; and the lateral regions are the *right* and *left lumbar*. The middle region of the lower zone is the *hypogastric*; and the lateral regions are the *right* and *left iliac* or *inguinal* (fig. 998).

The *pelvis* is that portion of the abdominal cavity which lies below and behind a plane passing through the promontory of the sacrum, the lineæ terminales of the hip-bones, and the pubic crests. It is bounded behind by the sacrum, coccyx, Piriformes, and the sacrospinous and sacrotuberous ligaments; in front and laterally by the ossa pubis and ischia and Obturatores interni; above it communicates with the abdomen proper; below it is closed by the Levatores ani and Coccygei and the urogenital diaphragm. The pelvis contains the urinary bladder, the sigmoid colon, the rectum, a few coils of the small intestine, and some of the generative organs.

When the anterior abdominal wall is removed, the viscera are partly exposed as follows: above and to the right side is the liver, situated chiefly under

* Symington (*Journal of Anatomy and Physiology*, vol. xlvii.) found that in a spare male subject the height of the abdominopelvic cavity, in a medial sagittal section, was 42 cm.; and that the anteroposterior diameter was 7 cm. opposite the twelfth thoracic vertebra, 3 cm. opposite the umbilicus and 12 cm. opposite the lower part of the sacrum. In a vertical section 3.5 cm. to the left of the median plane, "the abdominopelvic cavity is somewhat hourglass-shaped, the constriction of the cavity being due to the psoas muscle which attains its maximum forward projection at about the level of the umbilicus." In a vertical section through the left lateral plane of the abdomen the cavity is triangular in outline, with its concave base above; in this plane the upper part of the cavity has a maximum anteroposterior diameter of nearly 13 cm.

† *Journal of Anatomy and Physiology*, vol. xxvii.

‡ *Ibid.*, vols. xxxiii, xxxiv, xxxv.

the shelter of the right ribs and their cartilages, but extending across the middle line and reaching for some distance below the level of the xiphoid process. To the left of the liver is the stomach, from the lower border of which an apron-like fold of peritoneum, the *greater omentum*, descends for a varying distance, and obscures, to a greater or lesser extent, the other viscera. Below it, however,

FIG. 998.—Surface lines on the front of the thorax and abdomen.

some of the coils of the small intestine can generally be seen, while in the right iliac region the caecum, and, in the left iliac region, the iliac portion of the descending colon, are partly exposed. The bladder occupies the anterior part of the pelvis, and, if distended, will project above the symphysis pubis; the rectum lies in the concavity of the sacrum, but is usually obscured by coils of the small intestine. The sigmoid colon may lie between the rectum and the bladder.

When the stomach is followed from left to right it is seen to be continuous with the first part of the small intestine, or duodenum, the point of continuity being marked by a thickened ring which indicates the position of the pyloric

valve. The duodenum passes towards the under surface of the liver, and then, curving downwards, is lost to sight. If, however, the greater omentum and transverse colon be thrown upwards over the chest, the inferior part of the duodenum will be observed passing across the vertebral column towards the left side, where it becomes continuous with the coils of the jejunum and ileum. These measure about six metres in length, and if followed downwards the ileum is seen to end in the right iliac fossa by opening into the cæcum, the commencement of the large intestine. From the cæcum the large intestine takes an arch-like course, passing at first upwards on the right side, then across the middle line and downwards on the left side, and forming respectively the ascending, transverse, and descending parts of the colon. In the pelvis it assumes the form of a loop, termed the sigmoid colon, and ends in the rectum.

The spleen lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over towards the right side.

The glistening appearance of the deep surface of the abdominal wall and of the surfaces of the exposed viscera is due to the fact that the former is lined, and the latter are more or less completely covered, by a serous membrane, the *peritoneum*.

THE PERITONEUM

The *peritoneum* is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected over the contained viscera. In the female the free ends of the uterine tubes open into the peritoneal cavity. The part which lines the parietes is named the *parietal* portion of the peritoneum; that which is reflected over the contained viscera constitutes the *visceral* portion of the peritoneum. The *free surface* of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small quantity of serous fluid. Hence the viscera can glide freely on the wall of the cavity or on one another with the least possible amount of friction. The *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue, termed the *subserous areolar tissue*. The parietal portion is loosely connected with the fascial lining of the abdomen and pelvis, but is more closely adherent to the under surface of the Diaphragm, and also in the middle line of the anterior abdominal wall.

The parietal and visceral layers of the peritoneum are in actual contact, but the potential space between them is named the *peritoneal cavity*. The peritoneal cavity gives off a large diverticulum, the *omental bursa*, which is situated behind the stomach and adjoining structures; the neck or communication between the cavity and the bursa is termed the *epiploic foramen* (foramen of Winslow). Formerly the main portion of the cavity was described as the greater sac, and the omental bursa as the lesser sac of the peritoneum.

The peritoneum differs from the other serous membranes of the body in presenting a much more complex arrangement, and one that can only be clearly understood by following the development of the digestive tube. The student therefore is advised to preface his study of the peritoneum by reading the chapter dealing with this subject (p. 128).

To trace the membrane from one viscus to another, and from the viscera to the parietes, it is necessary to follow its continuity in the vertical and horizontal directions, and it will be found simpler to describe the main portion of the cavity and the omental bursa separately.

Vertical disposition of the main peritoneal cavity (greater sac) (fig. 999).—It is convenient to trace this from the back of the anterior abdominal wall at the level of the umbilicus. On following the peritoneum upwards from this level it is seen to be reflected around a fibrous cord, the *ligamentum teres*, or *obliterated umbilical vein*, which reaches from the umbilicus to the under surface of the liver. This reflection forms a somewhat triangular fold, the *falciform ligament of the liver*, attaching the upper and anterior surfaces of the liver to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the whole of the under surface of the anterior part of the Diaphragm, and is reflected from it on to the upper surface of the right lobe of the liver as the *superior layer of the coronary*

ligament, and on to the upper surface of the left lobe as the *superior layer of the left triangular ligament* of the liver. Covering the upper and anterior surfaces of the liver, it is continued round its sharp margin on to the under surface, where it presents the following relations: (a) It covers the under surface of the right lobe and is reflected from the back part of this on to the right suprarenal gland and upper extremity of the right kidney, forming in this situation the *inferior layer of the coronary ligament*; a special fold, the *hepatorenal ligament*, is frequently present between the inferior surface of the liver and the front of the kidney. From the kidney it is carried downwards to the duodenum and right colic flexure and medialwards in front of the inferior vena cava, where it is continuous with the posterior wall of the omental bursa. Between the two layers of the coronary ligament there is a large triangular surface of the liver devoid of peritoneal covering: this is named the *bare area* of the liver, and is attached to the Diaphragm by areolar tissue. Towards the right margin of the liver the two layers of the coronary ligament gradually approach each other, and ultimately fuse to form a small triangular fold connecting the right lobe of the liver to the Diaphragm, and named the *right triangular ligament* of the liver. The apex of the bare area corresponds with the point of meeting of the two layers of the coronary ligament, its base with the fossa for the inferior vena cava. (b) It covers the lower surface of the quadrate lobe, the under and lateral surfaces of the gall-bladder, and the under surface and posterior border of the left lobe; it is then reflected from the upper surface of the left lobe to the Diaphragm as the *inferior layer of the left triangular ligament*, and from the porta of the liver and the fossa for the ductus venosus to the lesser curvature of the stomach and the first 2.5 cm. of the duodenum as the anterior layer of the *hepatogastric* and *hepatoduodenal ligaments*, which together constitute the *lesser omentum*. If this layer of the lesser omentum be followed to the right it will be found to turn round the hepatic artery, bile-duct, and portal vein, and become continuous with the anterior wall of the omental bursa, forming a free folded edge of peritoneum. Traced downwards, the lesser omentum covers the anterosuperior surface of the stomach and the commencement of the duodenum, and is carried down into a large free fold, known as the *gastrocolic ligament* or *greater omentum*. Reaching the free margin of this fold, it is reflected upwards to cover the under and posterior surfaces of the transverse colon, and thence to the posterior abdominal wall as the inferior layer of the *transverse mesocolon*. It reaches the abdominal wall at the head and anterior border of the pancreas, is then carried down over the lower part of the head and over the inferior surface of the pancreas on the superior mesenteric vessels, and thence to the small intestine as the anterior layer of the *mesentery*. It encircles the intestine, and subsequently may be traced, as the posterior layer of the mesentery, upwards and backwards to the abdominal wall. From this it sweeps down over the aorta into the pelvis, where it invests the sigmoid (pelvic) colon, its reduplication forming the *sigmoid mesocolon* (pelvic mesocolon). Leaving first the sides and then the front of the rectum, it is reflected on to the seminal vesicles and the fundus of the urinary bladder, and after covering the upper surface of that viscus, is carried along the medial and lateral umbilical ligaments (fig. 1000) on to the back of the abdominal wall to the level from which a start was made.

Between the rectum and the bladder it forms, in the male, a pouch, the *rectovesical excavation*, the bottom of which is slightly below the level of the upper ends of the vesiculae seminales, and about 7.5 cm. from the orifice of the anus. When the bladder is distended, the peritoneum is carried up with it so that a considerable part of the anterior surface of the bladder lies directly against the abdominal wall without the intervention of peritoneal membrane. In the female the peritoneum is reflected from the rectum over the posterior vaginal fornix to the cervix and body of the uterus, forming the *recto-uterine excavation* or *pouch of Douglas*. It is continued over the intestinal surface and fundus of the uterus on to its vesical surface, which it covers as far as the junction of the body and neck of the uterus, and then to the bladder, forming here a second, but shallower, pouch, the *vesico-uterine excavation*. It is also reflected from the sides of the uterus to the lateral walls of the pelvis as two expanded folds, the *broad ligaments of the uterus*, in the free margin of each of which is the uterine tube.

Vertical disposition of the omental bursa (lesser sac) (fig. 999).—A start may be made in this case on the posterior abdominal wall at the anterior border of the pancreas. From this region the peritoneum may be followed upwards over the anterior surface of the pancreas on to the inferior surface of the Diaphragm, and thence on to the caudate lobe and caudate process of the liver to the fossa for the ductus venosus and the porta hepatis. Traced to the right, it is continuous over the inferior vena cava with the posterior wall of the main cavity. From the liver it is carried downwards to the lesser curvature of the stomach and the commencement of the duodenum as the

FIG. 999.—The vertical disposition of the peritoneum. (Main cavity, red; omental bursa, blue.)

posterior layer of the lesser omentum, and is continuous on the right, round the hepatic artery, bile-duct, and portal vein, with the anterior layer of this omentum. The posterior layer of the lesser omentum is carried down as a covering for the postero-inferior surface of the stomach and commencement of the duodenum, and is continued downwards as the deep layer of the gastro-colic ligament or greater omentum. From the free margin of this fold it is reflected upwards to the anterior and superior surfaces of the transverse colon, and thence as the superior layer of the transverse mesocolon to the anterior border of the pancreas, the level from which a start was made. It will be seen that the loop formed by the wall of the omental bursa below the transverse colon follows, and is closely applied to, the deep surface of that formed by the peritoneum of the main cavity, and that the greater omentum or large fold of peritoneum which hangs in front of the small intestine therefore consists of four layers, two anterior and two posterior, separated by the potential cavity of the omental bursa. The transverse colon lies between the two posterior layers.

Horizontal disposition of the peritoneum.—Below the transverse colon the arrangement is simple, as it includes only the main cavity; above

the level of the transverse colon it is more complicated on account of the existence of the omental bursa. Below the transverse colon it may be considered in the two regions, viz. in the pelvis and in the abdomen proper.

(1) *In the pelvis.*—The peritoneum here follows closely the surfaces of the pelvic viscera and the inequalities of the pelvic walls, and presents important differences in the two sexes. (a) *In the male* (fig. 1001) it encircles the sigmoid colon, from which it is reflected to the posterior wall of the pelvis as a fold, the *sigmoid mesocolon*. It leaves the sides and, finally, the front of the rectum,

FIG. 1000.—A posterior view of the lower part of the anterior abdominal wall. The peritoneum is in place, and the various cords are shining through. (After Joessel.)

and is continued over the upper parts of the seminal vesicles on to the upper surface of the bladder; on either side of the rectum it forms a fossa, the *pararectal fossa*, which varies in size with the distension of the rectum. In front of the rectum the peritoneum forms the rectovesical excavation, which is limited laterally by peritoneal folds extending from the sides of the bladder to the rectum and sacrum. These folds are known, from their position, as the *rectovesical* or *sacrogenital folds*. The peritoneum of the anterior pelvic wall covers the superior surface of the bladder, and on either side of this viscus forms a depression, termed the *paravesical fossa*, which is limited laterally by the fold of peritoneum covering the ductus deferens. The size of this fossa is dependent on the state of distension of the bladder; when the bladder is empty, a variable fold of peritoneum, the *plica vesicalis transversa*, divides the fossa into two portions. On the peritoneum between the paravesical and pararectal fossae the only elevations are those produced by the ureters and the hypogastric vessels. (b) *In the female*, pararectal and paravesical

fossæ similar to these in the male are present: the lateral limit of the paravesical fossa is the peritoneum investing the round ligament of the uterus. The rectovesical excavation is, however, divided by the uterus and vagina into a small anterior vesico-uterine and a large, deep, posterior recto-uterine excavation. The sacrogenital folds form the margins of the latter, and are continued on to the back of the uterus and the posterior fornix of the vagina as a transverse fold, the *torus uterinus*. The *broad ligaments* extend from the sides of the uterus to the lateral walls of the pelvis; they contain in their free margins the uterine tubes, and in their posterior layers the ovaries. Below, the broad ligaments are continuous with the peritoneum on the lateral walls of the pelvis. On the lateral pelvic wall behind the attachment of the broad

FIG. 1001.—The peritoneum of the male pelvis. (Dixon and Birmingham.)

ligament, in the angle between the elevations produced by the obliterated hypogastric artery and the ureter, is a slight fossa, the *ovarian fossa*, in which the ovary normally lies.

(2) *In the lower abdomen* (fig. 1002).—Starting from the linea alba, below the level of the transverse colon, and tracing the continuity of the peritoneum in a horizontal direction to the right, the membrane covers the inner surface of the abdominal wall almost as far as the lateral border of the Quadratus lumborum; it encloses the cæcum and vermiform process, and is reflected over the sides and front of the ascending colon; it may then be traced over the duodenum, Psoas major, and inferior vena cava towards the middle-line, whence it passes along the mesenteric vessels to invest the small intestine, and back again to the large vessels in front of the vertebral column, forming the *mesentery*, between the layers of which are contained the mesenteric blood-vessels, nerves, lacteals, and lymph-glands. It is then continued over the left Psoas major; it covers the sides and front of the descending colon, and, reaching the abdominal wall, is carried on it to the middle line.

(3) *In the upper abdomen* (fig. 1003).—Above the transverse colon the omental bursa is superadded to the general sac, and the communication of the two cavities with one another through the epiploic foramen can be demonstrated.

(a) *Main cavity*.—Commencing on the posterior abdominal wall at the inferior vena cava, the peritoneum may be followed to the right over the front of the right suprarenal gland and upper part of the right kidney on to the anterolateral abdominal wall. From the middle line of the anterior wall a backwardly directed fold encircles the obliterated umbilical vein and forms the falciform ligament of the liver. Continuing to the left, the peritoneum lines the anterolateral abdominal wall and covers the lateral part of the front of the left kidney, and is reflected to the posterior border of the hilum of the spleen as the posterior layer of the *phrenicocolic ligament* (lienorenal ligament). It can be traced round the surface of the spleen to the front of the hilum, and thence to the cardiac end of the greater curvature of the stomach as the anterior

FIG. 1002.—The horizontal disposition of the peritoneum in the lower part of the abdomen.

layer of the *gastrolieal ligament* (gastrosplenic omentum). It covers the anterosuperior surface of the stomach and commencement of the duodenum, and extends up from the lesser curvature of the stomach to the liver as the anterior layer of the lesser omentum.

(b) *Omental bursa*.—On the posterior abdominal wall the peritoneum of the general cavity is continuous with that of the omental bursa in front of the inferior vena cava. Starting from here, the bursa may be traced across the aorta and over the medial part of the front of the left kidney and Diaphragm to the hilum of the spleen as the anterior layer of the phrenicocolic ligament. From the spleen it is reflected to the stomach as the posterior layer of the gastrolieal ligament. It covers the postero-inferior surface of the stomach and commencement of the duodenum, and extends upwards to the liver as the posterior layer of the lesser omentum; the right margin of this layer is continuous round the hepatic artery, bile-duct, and portal vein with the wall of the main cavity. The lienal vessels run between the two layers of the phrenicocolic ligament, and the short gastric and left gastro-epiploic vessels between the two layers of the gastrolieal ligament.

The *epiploic foramen* (foramen of Winslow) (fig. 1076) is the communication between the main cavity and the omental bursa. It is bounded *in front* by the free border of the lesser omentum, with the common bile-duct, hepatic artery, and portal vein between its two layers; *behind* by the peritoneum covering the inferior vena cava; *above* by the peritoneum on the caudate

process of the liver; and *below* by the peritoneum covering the commencement of the duodenum and the hepatic artery, the latter passing forwards below the foramen before ascending between the two layers of the lesser omentum.

The boundaries and the extent of the omental bursa will now be evident. It is bounded *in front*, from above downwards, by the caudate lobe of the liver, the lesser omentum, the stomach, and the two anterior layers of the greater omentum. *Behind* it is limited, from below upwards, by the two posterior layers of the greater omentum, the transverse colon, and the ascending layer of the transverse mesocolon, the anterior surface of the pancreas, the left suprarenal gland, and the upper end of the left kidney. To the right of the oesophageal opening of the stomach it is bounded by that part of the Diaphragm which supports the caudate lobe of the liver and by the aorta and the inferior vena cava. Laterally, the bursa extends from the epiploic foramen to the spleen, where it is limited by the phrenocolical and gastrolenal ligaments.

FIG. 1003.—The horizontal disposition of the peritoneum in the upper part of the abdomen.

The omental bursa consists of a vestibule and three recesses, a superior, a middle and an inferior.

The *vestibule* is a narrow channel situated immediately to the left of the epiploic foramen, below the caudate process of the liver, above the head of the pancreas and superior part of the duodenum, and behind the hepatoduodenal ligament (p. 1094). The hepatic artery, portal vein, and common bile-duct pass forwards below the vestibule and then ascend between the two layers of the hepatoduodenal ligament. The *superior* recess extends upwards from the vestibule behind the porta hepatis and the caudate lobe of the liver, and in front of the Diaphragm and aorta. The *middle* recess, a small but variable pouch, descends between the lesser omentum and the pancreas. The vestibule and the superior and middle recesses together constitute the *bursa omenti minoris*. The *inferior* recess, or *bursa omenti majoris*, lies behind the stomach and extends as a large *lienal recess* between the stomach and the spleen. In the foetus the inferior recess reaches as low as the free margin of the greater omentum, but in the adult the vertical extent of the recess is much more limited owing to adhesions between the layers of the greater omentum.

The vestibule and the inferior recess may be shut off from one another by a complete *septum bursarum*, but in most cases they communicate through a rounded opening, the *foramen bursae omenti majoris*. This opening is limited

posteriorly by the *gastropancreatic ligament*, a sickle-shaped fold of peritoneum which encloses the left gastric artery, and extends from the tuber omentale of the pancreas to the back of the fundus of the stomach.

Crymble* states that two gastropancreatic ligaments can frequently be distinguished, viz. a *vertical* fold attaching the posterior border of the lesser curvature of the stomach to the Diaphragm and pancreas, and a *horizontal* fold between the pyloric part of the

FIG. 1004.—A diagram devised by Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

stomach and the pancreas. He gives as the boundaries of the foramen hursae omenti majoris, the lesser curvature of the stomach, the pancreas and the gastropancreatic ligaments. He found these ligaments absent in seven out of thirty five subjects.

During a considerable part of foetal life the transverse colon is suspended from the posterior abdominal wall by a mesentery of its own, the two posterior layers of the greater omentum passing at this stage in front of the colon (fig. 208). This condition occasionally persists throughout life, but as a rule adhesion occurs between the mesentery of the transverse colon and the posterior layer

* *Journal of Anatomy and Physiology*, vol. xlvii.

of the greater omentum, with the result that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold. In the adult the ommental bursa intervenes between the stomach and the structures on which that viscus lies, and performs therefore the functions of a serous bursa for the stomach.

Numerous peritoneal folds extend between the various organs or connect them to the parietes; they serve to hold the viscera in position, and, at the same time, enclose the vessels and nerves proceeding to them. They are grouped as ligaments, omenta, and mesenteries.

The ligaments will be described with their respective organs.

There are two omenta, the lesser and the greater.

The *lesser omentum* is the fold which extends to the liver from the lesser curvature of the stomach and the commencement of the duodenum. It is continuous with the two layers of peritoneum which cover respectively the anterosuperior and postero-inferior surfaces of the stomach and first part of the duodenum. When these two layers reach the lesser curvature of the stomach and the upper border of the duodenum, they unite and ascend as

FIG. 1005.—The superior and inferior duodenal fossæ. (Poirier and Charpy.)

a double fold to the porta hepatis; to the left of the porta hepatis the fold is attached to the bottom of the fossa for the ductus venosus, along which it is carried to the Diaphragm, where the two layers separate to embrace the end of the œsophagus. At the right border of the omentum the two layers are continuous, and form a free margin which constitutes the anterior boundary of the epiploic foramen. The portion of the lesser omentum extending between the liver and stomach is termed the *hepatogastric ligament*, while that between the liver and duodenum is the *hepatoduodenal ligament*. Between the two layers of the lesser omentum, close to the right free margin, are the hepatic artery, the common bile-duct, the portal vein, lymphatics, and the hepatic plexus of nerves—all these structures being enclosed in a *fibrous capsule* (Glisson's capsule). The right and left gastric arteries run between the layers of the lesser omentum, where these are attached to the stomach.

The *greater omentum* is the largest peritoneal fold. It consists of a double sheet of peritoneum, folded on itself so that it is made up of four layers. The two layers which descend from the stomach and commencement of the duodenum pass in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These individual layers may be easily demonstrated in the young subject, but in the adult they are more or less inseparably blended. The left border of the greater omentum is continuous with the gastroligament; its right border extends as far as the commencement of the duodenum. The

greater omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat people accumulates in considerable quantity. Between its two anterior layers, a short distance from the greater curvature of the stomach, is the anastomosis between the right and left gastro-epiploic vessels.

The *mesenteries* are: the mesentery (mesentery proper), the mesenteriole of the vermiform process, the transverse mesocolon, and the sigmoid mesocolon. In addition to these there are sometimes an ascending and a descending mesocolon.

The *mesentery* is a broad, fan-shaped fold of peritoneum connecting the convolutions of the jejunum and ileum with the posterior wall of the abdomen. Its *root*—the border connected with the structures in front of the vertebral column—is narrow, about 15 cm. long, and is directed obliquely from the

FIG. 1006.—The duodenojejunal fossa. (Poirier and Charpy.)

duodenojejunal flexure at the left side of the second lumbar vertebra to the right sacro-iliac articulation (fig. 1004). Its intestinal border is nearly 7 metres long; and here the two layers separate to enclose the intestine and form its peritoneal coat. It is short above, but lengthens rapidly to about 20 cm., and is thrown into numerous plaits or folds. It suspends the small intestine, and contains between its layers the jejunal and ileal branches of the superior mesenteric artery, with their accompanying veins and plexuses of nerves, the lacteal vessels, the mesenteric lymph-glands, and a varying amount of fatty tissue.

The *mesenteriole of the vermiform process* is attached to the back of the lower end of the mesentery, close to the ilcoecal junction, and passes behind the terminal part of the ileum to clothe the appendix. Between its layers are the blood-vessels, nerves and lymphatic vessels of the appendix together with a lymph-gland.

The *transverse mesocolon* is a broad fold connecting the transverse colon to the posterior wall of the abdomen. It is continuous with the two posterior layers of the greater omentum, which, after separating to surround the transverse colon, join behind it, and are continued to the vertebral column, where they diverge in front of the anterior border of the pancreas. This fold contains between its layers the vessels which supply the transverse colon.

The *sigmoid mesocolon* is a fold of peritoneum which retains the sigmoid colon in connexion with the pelvic wall. Its line of attachment forms a V-shaped curve, the apex of the curve being placed near the point of division of the left common iliac artery. The curve begins on the medial side of the left Psoas major, and runs upwards and backwards to the apex, from which

Fig. 1007.—Superior ilioecæal fossa. (Poirier and Charpy.)

it bends sharply downwards, and ends in the median plane at the level of the third sacral vertebra. The sigmoid and superior hæmorrhoidal vessels run between the two layers of this fold.

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon. Sometimes, however, these are surrounded by peritoneum and attached to the posterior abdominal wall by an ascending and a descending mesocolon respectively. A fold of peritoneum, the *phrenicocolic ligament*, is continued from the left colic flexure to the Diaphragm opposite

FIG. 1008.—Inferior ileocæcal fossa. The cæcum and ascending colon have been drawn lateralwards and downwards, the ileum upwards and backwards, and the vermiform process downwards. (Poirier and Charpy.)

the tenth and eleventh ribs; it passes below and serves to support the spleen, and therefore has received the name of *sustentaculum lienis*.

The *appendices epiploicæ* are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse and sigmoid parts of the colon.

Peritoneal recesses or fossæ.—In certain parts of the abdominal cavity there are recesses of peritoneum forming culs-de-sac or pouches, which are of surgical interest in connexion with the possibility of the occurrence of 'retro-peritoneal' herniæ. The largest of these is the omental bursa (already described), but several others, of smaller size, require mention, and may be divided into three groups, viz.: duodenal, cæcal, and intersigmoid.

1. *Duodenal fossæ* (figs. 1005, 1006).—Three are fairly constant, viz.: (a) The *inferior duodenal fossa*, present in from 70 to 75 per cent. of cases, is situated opposite the third lumbar vertebra, on the left side of the ascending portion of the duodenum. Its opening is directed upwards, and is bounded by a thin sharp fold of peritoneum with a concave margin, called the *duodeno-mesocolic fold*. The tip of the index finger introduced into the fossa under

FIG. 1009.—The cæcal fossa. The ileum and cæcum are drawn backwards and upwards. (Souligoux.)

the fold passes some little distance behind the ascending portion of the duodenum. (b) The *superior duodenal fossa*, present in from 40 to 50 per cent. of cases, often co-exists with the inferior, and its orifice looks downwards. It lies on the left of the ascending portion of the duodenum, in front of the second lumbar vertebra, and behind a sickle-shaped fold of peritoneum, the *duodenojejunal fold*, and has a depth of about 2 cm. (c) The *duodenojejunal fossa* exists in from 15 to 20 per cent. of cases, but has never yet been found in conjunction with the other forms of duodenal fossæ; it can be seen by pulling the jejunum downwards and to the right, after the transverse colon has been pulled upwards. It is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. It has a depth of from 2 cm. to 3 cm., and its orifice, directed downwards and to the right, is nearly circular and will admit the tip of the little finger.

2. *Cæcal fossæ.*—There are three principal pouches or recesses in the neighbourhood of the cæcum: (a) The *superior ileocaecal fossa* (fig. 1007) is formed by a fold of peritoneum, arching over the branch of the ileocolic artery which supplies the ileocolic junction. The fossa is a narrow chink situated between the mesentery of the small intestine, the ileum, and the small portion of the cæcum behind. (b) The *inferior ileocaecal fossa* (fig. 1008) is situated behind the angle of junction of the ileum and cæcum. It is formed by the *inferior*

ileocaecal fold of peritoneum (bloodless fold of Treves), the upper border of which is fixed to the ileum, opposite its mesenteric attachment, while the lower border, passing over the ileocaecal junction, joins the mesenteriole of the vermiform process, and sometimes the process itself. Between this fold and the mesenteriole of the vermiform process is the inferior ileocaecal fossa. It is bounded above by the posterior surface of the ileum and the mesentery; in front and below by the ileocaecal fold, and behind by the upper part of the mesenteriole of the vermiform process. (c) The *cæcal fossa* (fig. 1009) is situated immediately behind the cæcum, which has to be raised to bring it into view. It varies much in size and extent. In some cases it is sufficiently large to admit the index finger, and extends upwards behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. It is bounded on the right by the cæcal fold, which is attached by one edge to the abdominal wall from the lower border of the kidney to the iliac fossa, and by the other to the posterolateral aspect of the colon. In some instances additional fossæ, the *retrocæcal fossæ*, are present.

3. The *intersigmoid fossa* is constant in the foetus and during infancy, but disappears in a certain percentage of cases as age advances. Upon drawing the sigmoid colon upwards, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the intersigmoid fossa, which lies behind the sigmoid mesocolon, and in front of the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, in others it will admit the whole of the index finger.

Applied Anatomy.—Any of these fossæ may be the site of a 'retroperitoneal' hernia. The cæcal fossæ are of especial interest, because hernia of the vermiform process frequently takes place in one of them, and it may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the vermiform process, where it travels upwards behind the ascending colon as far as the Diaphragm.*

THE STOMACH (VENTRICULUS)

The **stomach** is the most dilated part of the digestive tube, and is situated between the end of the œsophagus and the beginning of the small intestine. It lies in the epigastric, umbilical, and left hypochondriac regions of the abdomen, and occupies a recess bounded by the upper abdominal viscera, and completed in front and on the left side by the anterior abdominal wall and the Diaphragm.

The *shape and position* of the stomach are so greatly modified by changes within itself and in the surrounding viscera that no one form can be described as typical. The chief modifications are determined by (1) the amount of the stomach contents, (2) the stage which the digestive process has reached, (3) the degree of development of the gastric musculature, and (4) the condition of the adjacent intestines. It is, however, possible by comparing a series of stomachs, which have been hardened in situ, to determine certain markings more or less common to all (fig. 1010).

The stomach presents two openings, two borders or curvatures, and two surfaces.

Openings.—The opening by which the œsophagus communicates with the stomach is known as the *cardiac orifice*, and is situated on the left of the middle line at the level of the tenth thoracic vertebra. The short abdominal portion of the œsophagus (*antrum cardiacum*) is conical in shape and curved sharply to the left, the base of the cone being continuous with the cardiac orifice of the stomach. The right margin of the œsophagus is continuous with the lesser curvature of the stomach, while the left margin joins the greater curvature at an acute angle, termed the *incisura cardiaca*.

The *pyloric orifice* communicates with the duodenum, and its position is usually indicated on the surface of the stomach by a circular groove, the

* On the anatomy of these fossæ, see the *Arrie and Gale Lectures* by Maynard, 1890.

duodenopyloric constriction. This orifice lies to the right of the middle line at the level of the upper border of the first lumbar vertebra.

Curvatures.—The *lesser curvature*, extending between the cardiac and pyloric orifices, forms the right or posterior border of the stomach. It descends as a continuation of the right margin of the oesophagus in front of the fibres of the right crus of the Diaphragm, and then, turning to the right, it crosses the first lumbar vertebra and ends at the pylorus. Nearer its pyloric than its cardiac end is a well-marked notch, the *incisura angularis*, which varies somewhat in position with the state of distension of the viscus; it serves to separate the stomach into a right and a left portion. The lesser curvature gives attachment to the two layers of the hepatogastric ligament, and between these two layers are the right and left gastric arteries.

The greater curvature is directed mainly forwards, and is four or five times as long as the lesser curvature. Starting from the cardiac orifice at the *incisura cardiaca*, it forms an arch backwards, upwards, and to the left; the highest point of the convexity is on a level with the sixth left costal cartilage. From this level it may be followed downwards and forwards, with a slight convexity to the left as low as the cartilage of the ninth rib; it then turns to the right,

FIG. 1010.—An outline of the stomach, showing its anatomical landmarks.

to end at the pylorus. Directly opposite the *incisura angularis* of the lesser curvature the greater curvature presents a dilatation, which is the left extremity of the *pyloric part*; this dilatation is limited on the right by a slight groove, the *sulcus intermedius*, which is about 2.5 cm. from the duodenopyloric constriction. The portion between the sulcus intermedius and the duodenopyloric constriction is termed the *pyloric antrum*. At its commencement the greater curvature is covered by peritoneum continuous with that on the front of the stomach. The left part of the curvature gives attachment to the gastrolenal ligament, while to its anterior portion are attached the two layers of the greater omentum, separated from each other by the gastro-epiploic vessels.

Surfaces.—When the stomach is in the contracted condition, its surfaces are directed upwards and downwards respectively, but when the viscus is distended they look forwards and backwards. They may therefore be described as anterosuperior and postero-inferior.

Anterosuperior surface.—The left half of this surface is in contact with the Diaphragm, which separates it from the base of the left lung, the pericardium, and the seventh, eighth, and ninth ribs and intercostal spaces of the left side. The right half is in relation with the left and quadrate lobes of the liver and with the anterior abdominal wall. When the stomach is empty, the transverse colon may lie on the front part of this surface. The whole surface is covered by peritoneum.

The postero-inferior surface is in relation with the Diaphragm, the spleen, the left suprarenal gland, the upper part of the front of the left kidney, the anterior surface of the pancreas, the left colic flexure, and the upper layer of the transverse mesocolon. These structures form a shallow bed, the *stomach*

bed, on which the viscus rests. The transverse mesocolon separates the stomach from the duodenojejunal flexure and small intestine. The postero-inferior surface is covered by peritoneum, except over a small area close to the cardiac orifice; this area is limited by the lines of attachment of the *gastrophrenic ligament*, and lies in apposition with the Diaphragm, and frequently with the upper portion of the left suprarenal gland.

FIG. 1011.—A diagram showing the shape and position of the empty stomach. Erect posture. (After Hertz.)

FIG. 1012.—A diagram showing the shape and position of the distended stomach. Erect posture. (After Hertz.)

FIG. 1013.—A diagram showing the shape and position of the moderately filled stomach. Erect posture. (After Hertz.)

Component parts of the stomach.—A plane passing through the incisura angularis on the lesser curvature and the left limit of the opposed dilatation on the greater curvature divides the stomach into a left portion or *body* and a right or *pyloric portion*. The upper portion of the body is known as the *fundus*, and is marked off from the remainder of the body by a plane passing horizontally through the cardiac orifice. The pyloric portion is divided by a plane through the sulcus intermedius at right angles to the long axis of this portion; the part to the right of this plane is the *pyloric antrum* (fig. 1010).

By means of x-rays the form and position of the stomach can be studied in the living subject after the administration of a meal containing bismuth. During the process of digestion, it will be found divided by a muscular constriction into a large dilated left portion, and a narrow contracted tubular right portion. The constriction is in the body of the stomach, and does not follow any of the anatomical landmarks; indeed, it shifts gradually towards the left as digestion progresses, i.e. more of the body is gradually absorbed into the tubular part. The position of the stomach varies with the posture, with the amount of the stomach contents, and with the condition of the intestines on which it rests (figs. 1011 to 1013). In the erect posture the empty stomach is somewhat J-shaped; the part above the cardiac orifice is usually distended with gas; the pylorus descends to the level of the second lumbar vertebra, and the most dependent part of the stomach is at the level of the umbilicus. Variation in the amount of its contents affects mainly the cardiac portion, the pyloric portion remaining in a more or less contracted condition during the process of digestion. As the stomach fills it tends to expand forwards and downwards in the direction of least resistance, but when this is interfered with by a distended condition of the colon or intestines the fundus presses upwards on the liver and Diaphragm and gives rise to the feelings of oppression and palpitation complained of in such cases. His* and Cunningham† have shown by hardening the viscera *in situ* that the contracted stomach has a sickle shape, the fundus looking directly backwards. The surfaces are directed upwards and downwards, the upper surface having, however, a gradual downward slope to the right. The greater curvature is in front and at a slightly higher level than the lesser.

The position of the full stomach depends, as already indicated, on the state of the intestines: when these are empty the fundus expands vertically and also forwards, the pylorus is displaced towards the right, and the whole organ assumes an oblique position, so that its surfaces are directed more forwards and backwards. The lowest part of the stomach is at the pyloric vestibule, which reaches to the region of

the umbilicus. Where the intestines interfere with the downward expansion of the fundus the stomach retains the horizontal position which is characteristic of the contracted viscus.

Interior of the stomach.—When examined after death, the stomach is usually fixed

* *Archiv für Anatomie und Physiologie, anat. Abth.*, 1903.

† *Transactions of the Royal Society of Edinburgh*, vol. xlv. part i.

at some temporary stage of the digestive process. A common form is that shown in fig. 1014. If the viscus be laid open by a section through the plane of its two curvatures, it is seen to consist of two segments: (a) a large globular portion on the left and (b) a narrow tubular part on the right. These are separated by a constriction which indents the body and greater curvature, but does not involve the lesser curvature. To the left

FIG. 1014.—The interior of the stomach.

of the cardiac orifice is the incisura cardiaca: the projection of this notch into the cavity of the stomach increases as the organ distends, and has been supposed to act as a valve preventing regurgitation into the œsophagus. In the pyloric portion are seen: (a) the elevation corresponding to the incisura angularis, and (b) the circular projection from the duodenopyloric constriction which forms the pyloric valve; the separation of the pyloric antrum from the rest of the pyloric part is scarcely indicated.

F. T. Lewis* has modelled the gastric epithelium in the human embryo, and has shown that a canal (named by him the *gastric canal*) extends along the lesser curvature from the antrum cardiacum to the incisura angularis (fig. 1015), the distinctness of the canal being strikingly shown when the model is viewed from the inside. Jefferson† has brought forward radiographic evidence to show that such a canal exists in the adult. He found that in eighteen out of twenty-two cases examined whilst in the act of swallowing a mixture of oxychloride of bismuth and milk the fluid was confined to the lesser curvature. He is of the opinion that the oblique muscular coat of the stomach is so arranged that by its contraction it will cause a temporary cutting off of a canal along the lesser curvature.

FIG. 1015. —Diagram showing the subdivisions of the human stomach. (F. T. Lewis.)

The *pyloric valve* is a muscular ring composed of a thickened portion of the circular layer of the muscular coat; this ring is covered by a reduplication of the mucous membrane. Some of the deeper longitudinal fibres turn in and interlace with the circular fibres of the valve.

Structure.—The wall of the stomach consists of four coats: serous, muscular, areolar, and mucous, together with vessels and nerves.

* The *serous coat* is derived from the peritoneum, and covers the entire surface of the organ, excepting along the greater and lesser curvatures at the lines of attachment of

* *American Journal of Anatomy*, vol. xiii.

† *Journal of Anatomy and Physiology*, vol. xlix.

the greater and lesser omenta; here the two layers of peritoneum leave a small space, triangular in section, along which the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice, there is also a small area uncovered by peritoneum, where the organ is in contact with the under surface of the Diaphragm.

FIG. 1016.—The longitudinal and circular muscular fibres of the stomach, viewed from above and in front. (Spalteholz.)

FIG. 1017.—The oblique muscular fibres of the stomach, viewed from above and in front. (Spalteholz.)

The muscular coat (figs. 1016, 1017) is situated immediately beneath the serous covering, with which it is closely connected. It consists of three layers of unstriped muscular fibres: longitudinal, circular, and oblique.

The *longitudinal fibres* are the most superficial, and are arranged in two sets. The first set consists of fibres continuous with the longitudinal fibres of the œsophagus; they radiate from the cardiac orifice and end proximally to the pyloric portion. The second set commences on the body of the stomach and passes to the right, its fibres becoming more thickly arranged as they approach the pylorus. Some of the more superficial fibres of this set pass on to the duodenum, but the deeper fibres dip inwards and interlace with the circular fibres of the pyloric valve.

The *circular fibres* form a uniform layer over the whole extent of the stomach beneath the longitudinal fibres. At the pylorus they are most abundant, and are aggregated into a circular ring, which forms the *pyloric valve*. They are continuous with the circular fibres of the œsophagus, but are sharply marked off from the circular fibres of the duodenum by a *connective tissue septum*. Owing to the abrupt change in the thickness of the muscular coat at the pyloroduodenal junction, the pyloric wall forms a projection into the lumen of the duodenum.

FIG. 1018.—A section through the mucous membrane of a human stomach, near the cardiac orifice. $\times 45$. (v. Ebner, after J. Schaffer.)

c. Cardiac glands. d. Their ducts. cr. Gland similar to the intestinal glands, with goblet-cells. mm. Mucous membrane. m. Muscularis mucosae. m'. Muscular tissue within the mucous membrane.

The *oblique fibres*, internal to the circular layer, are limited chiefly to the body of the stomach. They sweep downwards from the incisura cardiaca and run more or less parallel with the lesser curvature. On the right they present a free and well-defined margin (fig. 1017); on the left they blend with the circular fibres.

The *areolar or submucous coat* consists of loose, areolar tissue, connecting the mucous and muscular layers.

The *mucous membrane* is thick and its surface is smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown colour over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker towards the pylorus. During the contracted state of the organ it is thrown into numerous folds or *rugae*, which for the most part have a longitudinal direction, and are best marked towards the pyloric end of the stomach, and along the greater curvature (fig. 1014). These folds are obliterated when the organ is distended.

Structure of the mucous membrane.—When examined with a lens, the inner surface of the mucous membrane presents a peculiar honeycomb appearance from being covered with small shallow depressions or *alveoli*, of a polygonal or hexagonal form, which vary from 0.12 mm. to 0.25 mm. in diameter. These are the ducts of the gastric glands, and at the bottom of each may be seen one or more minute orifices, the openings of the gland-tubes. The surface of the mucous membrane is covered by a single layer of columnar epithelium with occasional goblet cells. This epithelium commences very abruptly at the cardiac orifice, where there is a sudden transition from the stratified epithelium of the œsophagus.

The epithelial lining of the gland ducts is of the same character and is continuous with the general epithelial lining of the stomach (fig. 1020).

The gastric glands are of three kinds: (a) *cardiac*, (b) *fundus* or *oxyntic*, and (c) *pyloric*. The *cardiac glands* (fig. 1018), few in number, occur close to the cardiac orifice. They are of two kinds: (1) simple tubular glands resembling those of the pyloric end of the stomach, but with short ducts; (2) compound racemose glands resembling the duodenal glands. The *fundus glands* (fig. 1019) are found in the body and fundus of the stomach; they are simple tubes, two or more of which open into a single duct. The duct is short, sometimes not amounting to more than one-sixth of the whole length of the gland. Their epithelium consists of (1) short columnar, granular cells, known as the

FIG. 1019.—A fundus gland.

A. Transverse section of gland.

FIG. 1020.—A pyloric gland, from a section of the dog's stomach. (Ebstein.) (From Quain's Elements of Anatomy, Vol. II. Pt. I.)

m. Mouth. n. Neck. tr. A deep portion of a tubule cut transversely.

chief or central cells, and (2) larger, oval cells, termed *parietal* or *oxyntic* cells. These lie between the chief cells and the basement membrane, and stain deeply with eosin; they do not form a continuous layer but occur at intervals and so give the tube a beaded appearance. They are connected with the lumen of the gland by fine channels which run in the substance of the cells. The *pyloric glands* (fig. 1020) are found in the pyloric portion of the stomach. Each consists of two or three short tubes opening into a funnel-shaped duct. The tubes are convoluted and are about one-half the length of the duct; they are lined by cubical cells which are finely granular. Between the glands the mucous membrane consists of a connective tissue framework, with lymphoid tissue. In places, this latter tissue, especially in early life, is collected into little masses, which resemble the solitary lymphatic nodules of the intestine, and are termed the *lenticular glands* of the stomach. They are not, however, so distinctly circumscribed as the solitary nodules. The mucous membrane is bounded on its deep surface by a thin stratum of involuntary muscular fibre (*muscularis mucosae*), which in some parts consists only of a single longitudinal layer; in others of two layers, an inner circular and an outer longitudinal.

Vessels and Nerves.—The *arteries* supplying the stomach are: the left gastric, the right gastric and right gastro-epiploic branches of the hepatic, and the left gastro-epiploic and short gastric branches of the lienal. They supply the muscular coat, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upwards between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes, and also form hexagonal meshes around the ducts. From these the *veins* arise, and pursue a straight course downwards, between the tubules, to the submucous tissue; they end either in the lienal and superior mesenteric veins, or directly in the portal vein. The *lymphatic vessels* are numerous: they consist of a superficial and a deep set, and pass to the lymph-glands found along the two curvatures of the organ (p. 730). The *nerves* are the terminal branches of the right and left vagi, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the cardiac plexus of the sympathetic are also distributed to it. Nerve-plexuses are found in the submucous coat and between the layers of the muscular coat, as in the intestine. From these plexuses fibrils are distributed to the muscular tissue and the mucous membrane.

Applied Anatomy.—Operations on the stomach are frequently performed. By 'gastrotomy' is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterwards closed—in contradistinction to 'gastrostomy,' the making of a more or less permanent fistulous opening for purposes of feeding, when the patient cannot obtain sufficient nourishment owing to some form of œsophageal obstruction.

In cases of gastric ulcer perforation of the stomach not infrequently takes place. By opening the abdomen and closing the perforation, the vast majority of cases are cured, provided the operation is done not longer than twelve or fifteen hours after the perforation has taken place. The opening, which is generally situated on the anterior surface of the stomach near the pylorus, is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lembert's sutures. Free drainage of the peritoneal cavity should be established at the same time.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favourable, and, in cases of cancer of the pylorus, before operative proceedings are undertaken, the tumour has become so fixed and has so far implicated surrounding parts that removal of the pylorus is impossible and *gastro-enterostomy* has to be substituted. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible. It gives great relief in any form of obstruction to the pylorus, especially when associated with dilatation of the stomach. In this operation either the anterior or the posterior surface of the stomach may be anastomosed to the jejunum, the latter for preference, in which case an opening has first to be made through the transverse mesocolon in order to reach the lesser sac. This opening must particularly avoid the middle colic vessels. In cases of cancer of the stomach involving other parts than the pylorus, the question of removing the whole or greater part of the stomach has to be considered.

Hypertrophy and spasm of the circumferential muscular coat of the pylorus coming on during the first few weeks or months of life, and somewhat erroneously described as *congenital hypertrophic stenosis of the pylorus*, is a serious disorder of infancy. It is characterised by abdominal pains and obstinate vomiting coming on after food has been given. Gastric peristalsis can be observed by inspection of the child's epigastrium after it has been fed and before vomiting has occurred. Progressive wasting from want of nourishment, and death from exhaustion, tend to ensue. Gastro-enterostomy gives favourable results in a small proportion of cases.

The stomach is seldom ruptured from external violence, on account of its protected position. If it occurs, it is when the organ is distended with food. The stomach is sometimes injured in gunshot wounds. There is intense shock and severe pain, localised at first at the seat of the injury, but soon radiating over the whole abdomen. The treatment consists in opening the peritoneal cavity, clearing away all the extruded contents of the stomach, and repairing the rent.

THE SMALL INTESTINE (INTESTINUM TENUE)

The small intestine is a convoluted tube, extending from the pylorus to the colic valve, where it joins the large intestine. It is about 7 metres long,* and gradually diminishes in diameter from its commencement to its termination.

* Treves states that, in one hundred cases, the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches, and 15 feet 6 inches. He states that in the adult the length of the bowel is independent of age, height, and weight.

It is contained in the central and lower parts of the abdominal cavity and is surrounded above and at the sides by the large intestine; it is in relation, in front, with the greater omentum and abdominal parietes; a portion of it extends below the superior aperture of the pelvis and lies in front of the rectum. The small intestine consists of (1) a short, curved portion which is devoid of a mesentery and is named the duodenum, and (2) a long, greatly coiled part which is attached to the posterior abdominal wall by the mesentery (p. 1095), and is named the *intestinum tenue mesenteriale*; the proximal two-fifths of the latter constitute the jejunum (*intestinum jejunum*), the distal three-fifths the ileum (*intestinum ileum*).

The **duodenum** (fig. 1021) is so named because its length is about equal to the breadth of twelve fingers (25 cm.). It is the shortest, widest, and most fixed part of the small intestine; it has no mesentery, and is only partially

FIG. 1021. — The duodenum and pancreas.

covered by peritoneum. Its course presents a remarkable curve, somewhat of the shape of an imperfect circle, so that its termination is not far removed from its starting-point.

It commences at the pylorus, passes backwards, upwards and to the right, beneath the quadrato lobe of the liver to the neck of the gall-bladder, varying slightly in direction according to the degree of distension of the stomach; it then makes a sharp curve (superior duodenal flexure) and descends along the right margin of the head of the pancreas, for a variable distance, generally to the level of the upper border of the body of the fourth lumbar vertebra. It now makes a second bend (inferior duodenal flexure), and passes almost horizontally from right to left across the vertebral column, having a slight inclination upwards; and on the left side of the vertebral column it ascends for about 2.5 cm., and then ends opposite the second lumbar vertebra in the jejunum. At its union with the jejunum it turns abruptly forwards, forming the *duodenojejunal flexure*. For descriptive purposes it is divided into superior, descending, horizontal, and ascending portions.

Relations.—The *superior portion* is about 5 cm. long, and is the most movable of the four portions; it begins at the pylorus, and ends at the neck of the gall-bladder. It is covered by peritoneum with the exception of a small part of its posterior surface near the neck of the gall-bladder and the inferior

vena cava; the hepatoduodenal ligament is attached to the upper border, and the greater omentum to the lower border of the proximal half. It is in relation above and in front with the quadrato lobe of the liver and the gall-bladder; behind with the gastroduodenal artery, the common bile-duct, and the portal vein; and below and behind with the head and neck of the pancreas. It is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface.

The *descending portion*, from 7 cm. to 10 cm. long, extends from the neck of the gall-bladder, on a level with the first lumbar vertebra, along the right side of the vertebral column as low as the upper border of the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is here uncovered by peritoneum and

FIG. 1022.—The interior of the descending portion of the duodenum, showing the bile-papilla.

is connected to the duodenum by a small quantity of connective tissue. The parts above and below the transverse colon are covered in front by peritoneum, the part below by the right leaf of the mesentery. Posteriorly, it is not covered by peritoneum. It is in relation, in front, from above downwards, with the duodenal impression on the right lobe of the liver, the transverse colon, and the small intestine; behind, it has a variable relation to the front of the right kidney in the neighbourhood of its hilum, and is connected to it by loose areolar tissue; the renal vessels, the inferior vena cava, and the Psoas below, are also behind it. At its medial side is the head of the pancreas, and the common bile-duct; to its lateral side is the right colic flexure. The common bile-duct and the pancreatic duct together perforate the medial side of this portion of the intestine obliquely (figs. 1022, 1044), from 7 cm. to 10 cm. below the pylorus; the accessory pancreatic duct, when present, pierces it about 2 cm. above and slightly in front of these.

The *horizontal portion*, from 5 cm. to 7.5 cm. long, begins at the right side of the upper border of the fourth lumbar vertebra and passes from right to left, with a slight inclination upwards, in front of the great vessels and the crura of the Diaphragm, and ends in the ascending portion in front of the abdominal aorta. It is crossed from above downwards by the superior mesenteric vessels and the mesentery. Its anterior surface is covered by peritoneum, except near

the middle line, where it is crossed by the superior mesenteric vessels. Its posterior surface is uncovered by peritoneum, except towards its left extremity, where the posterior layer of the mesentery sometimes covers it to a variable extent. This surface rests upon the right crus of the Diaphragm, the inferior vena cava, and the aorta. The upper surface is in relation with the head of the pancreas.

The *ascending portion*, about 2·5 cm. long, ascends on the left side of the aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly forwards (*duodenojejunal flexure*) and is continuous with the jejunum. It lies in front of the left Psoas major and left renal vessels, and is covered in front, and partly at the sides, by peritoneum continuous with the left portion of the mesentery.

The superior part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed, and is bound down to neighbouring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the ascending part of the duodenum and the duodenojejunal flexure are fixed by a structure to which the name of *Musculus suspensorius duodeni* has been given. This muscle arises from the right crus of the Diaphragm, close to the right margin of the œsophagus. It passes downwards and slightly forwards in close relation with the celiac artery (sometimes dividing to enclose this vessel) and is attached to the posterior aspect of the upper part of the duodenojejunal flexure, many fibres being continued into the mesentery.* It possesses, according to Treitz, plain muscular fibres mixed with the fibrous tissue of which it is principally made up.

Crymble† confirms the observations of Treitz that this muscle consists of three parts, viz. an upper of striped muscular fibres, an intermediate elastic tendon, and a lower of unstriped muscular fibres.

Vessels and Nerves.—The *arteries* supplying the duodenum are the right gastric and superior pancreaticoduodenal branches of the hepatic, and the inferior pancreaticoduodenal branch of the superior mesenteric. The *veins* end in the liver and superior mesenteric veins. The *nerves* are derived from the celiac plexus.

The **mesenteric part** of the small intestine (*intestinum tenue mesenteriale*), about $6\frac{1}{2}$ metres long, is attached to the posterior abdominal wall by the mesentery, and extends from the duodenojejunal flexure to the colic valve where it ends in the cæcum of the large intestine. It is divided into jejunum and ileum, the former term being given to the upper two-fifths and the latter to the lower three-fifths. There is no morphological line of distinction between the two, and the division is arbitrary; but at the same time the character of the intestine gradually undergoes a change from the commencement of the jejunum to the end of the ileum, so that portions of the bowel taken from these two situations present characteristic and marked differences.

The **jejunum** (*intestinum jejunum*) is wider, its diameter being about 4 cm., and is thicker, more vascular, and of a deeper colour than the ileum. The circular folds or *valvulae conniventes* (p. 1110) of its mucous membrane are large and thickly set, and its villi are larger than in the ileum. The aggregated lymph-nodules are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. By grasping the jejunum between the finger and thumb the circular folds can be felt through the walls of the gut; these being absent from the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

The **ileum** (*intestinum ileum*) is narrower, its diameter being 3·75 cm., and its coats are thinner than those of the jejunum. It possesses few circular folds, and they are small and disappear entirely towards its lower end, but aggregated lymph-nodules (Peyer's patches) are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum lies chiefly in the umbilical, hypogastric, right iliac, and pelvic

* A. Low (*Journal of Anatomy and Physiology*, vol. xlii.).

† *British Medical Journal*, 1910, vol. ii. p. 1156.

regions. The terminal part of the ileum usually lies in the pelvis, from which it ascends over the right Psoas major and right iliac vessels; it ends in the right iliac fossa by opening into the medial side of the cæcum.

The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the *mesentery*, which allows of very free motion,

FIG. 1028.—A section of the duodenum of a cat. $\times 60$. (From Schäfer's Essentials of Histology.)

so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its vertebral border or root, about 15 cm. long, is attached to the posterior abdominal wall along a line running from the left side of the body of the second lumbar vertebra to the right sacro-iliac articulation, and crossing successively the horizontal part of the duodenum, the aorta, the inferior vena cava, the right ureter, and right Psoas major (fig. 1004). Its breadth from the vertebral to the intestinal border averages about 20 cm., and is greater in the middle than at its upper and lower ends; according to Lockwood it tends to increase as age advances. Between the two layers of which the

mesentery is composed are contained the jejunum, ileum, the jejunal and ileal branches of the superior mesenteric blood-vessels, nerves, lacteals, and lymph-glands, together with a variable amount of fat.

Meckel's diverticulum.—This is a pouch which projects from the lower part of the ileum in about 2 per cent. of subjects. Its average position is about 1 metre above the colic valve, and its average length about 5 cm. Its calibre is generally similar to that of the ileum, and its blind extremity may be free or may be connected with the abdominal wall or with some other portion of the intestine by a fibrous band. It represents the remains of the proximal part of the vitelline duct, the duct of communication between the yolk-sac and the primitive digestive tube in early fetal life.

Structure.—The wall of the small intestine (fig. 1023) is composed of four coats: serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum. The superior portion of the duodenum is almost completely surrounded by this membrane near its pyloric end, but is

FIG. 1024.—A vertical section through a villus of the small intestine of a dog. $\times 80$.

only covered in front at the other extremity; the descending portion is covered by it in front, except where it is carried off by the transverse colon; and the inferior portion lies behind the peritoneum, which is separated from it in and near the middle line by the superior mesenteric vessels. The rest of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to enter the wall of the gut.

The *muscular coat* consists of two layers of unstripped muscular fibres: an external longitudinal, and an internal circular. The *longitudinal layer* is thin: the *circular layer* is thick and is composed of unstripped muscular fibres of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The *areolar or submucous coat* unites the mucous and muscular layers. It consists of loose, areolar tissue containing the larger blood-vessels, lymphatics, and nerves.

The *mucous membrane* is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is the *muscularis mucosa*, a double layer of unstripped muscular fibres, outer longitudinal and inner circular; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph-corpuscles, and in this the blood-vessels and nerves ramify; lastly, a basement membrane, supporting a single layer of tall columnar cells. The cells are granular in appearance, and each possesses a clear oval nucleus. At their superficial or unattached ends they present a distinct layer of highly refracting material, marked by vertical striae (the *striated border*). Goblet cells occur at intervals in the epithelial layer.

Contained within or belonging to the mucous membrane are the following structures:

- ✓ Circular folds.
- ✓ Villi.
- ✓ Intestinal glands.
- ✓ Duodenal glands.
- ✓ Solitary lymphatic nodules.
- ✓ Aggregated lymphatic nodules.

The *circular folds* or *valvulae conniventes* are large valvular flaps projecting into the lumen of the bowel. They are composed of reduplications of the mucous membrane, the two layers of the fold being bound together by submucous tissue; unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely round the intestine for about one-half or two-thirds of its circumference, but some form complete circles, some bifurcate and join adjacent folds, and others have a spiral direction; the latter usually extend a little more than once round the bowel, but occasionally two or three times. The larger folds are about 8 mm. in depth at their broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. Circular folds are not found at the commencement of the duodenum, but begin to appear about 2.5 or 5 cm. beyond the pylorus. In

the lower part of the descending portion, below the point where the bile- and pancreatic ducts enter the intestine, they are very large and closely approximated. In the horizontal and ascending portions of the duodenum and upper half of the jejunum they are large and numerous, but from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine, as compared with the duodenum and jejunum. The circular folds retard the passage of the food along the intestine, and afford an increased surface for absorption.

The intestinal villi are highly vascular processes, just visible with the naked eye: they project from the mucous membrane of the small intestine throughout its whole extent, and give to its surface a velvety appearance. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum.

Structure of the villi (figs. 1024, 1025).—The essential parts of a villus are: the lacteal vessel, the blood-vessels, the epithelium, the basement membrane and the muscular tissue of the mucosa, all being supported and held together by retiform lymphoid tissue.

The *lacteals* are in some cases double, and in some animals multiple, but usually there is a single vessel. Situated in the axis of the villus each commences by a dilated blind

FIG. 1025.—A transverse section through a villus of the human intestine. $\times 350$. (v. Ebner.)

a. Basement membrane, here somewhat shrunken away from the epithelium. b. Lacteal. c. Columnar epithelium; d. its striated border. e. Goblet-cells. f. Leucocytes in epithelium. f'. Leucocyte below epithelium. g. Blood-vessels. h. Muscle-cells cut across.

FIG. 1026.—The villi of the small intestine, showing the blood-vessels and the lymphatic vessels. (Cadiat.)

extremity near to, but not quite at, the summit of the villus. The wall is composed of a single layer of endothelial cells.

The *muscular fibres* are derived from the *muscularis mucosæ*, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off, laterally, individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement membrane and to the lacteal.

FIG. 1027.—An intestinal gland from the human intestine. (Flemming.) (From Quain's Elements of Anatomy, Vol. II. Pt. I.)

The *blood-vessels* (fig. 1026) form a plexus under the basement membrane, and are enclosed in the reticular tissue.

These structures are surrounded by the *basement membrane*, which is made up of a stratum of endothelial cells, and upon this is placed a layer of *columnar epithelium*, the characteristics of which have been described on p. 1110. The *retiform tissue* forms a network (fig. 1025) in the meshes of which a number of leucocytes are found.

The *intestinal glands* (crypts of Lieberkühn) (fig. 1027) are found in considerable numbers over every part of the mucous membrane of the small intestine. They are simple tubular glands, arranged perpendicularly to the surface, upon which they open by small circular apertures. Their orifices may be seen with the aid of a lens as minute dots scattered between the villi. Their walls are thin, consisting of a basement membrane lined by columnar epithelium, and covered on their exterior by capillary vessels.

The *duodenal glands* (Brunner's glands) are limited to the duodenum (fig. 1023), and are found in the submucous areolar tissue. They are largest and most numerous near the pylorus, forming an almost complete layer in the superior portion and upper half of the descending portion of the duodenum. They then begin to diminish in number, and disappear at the junction of the duodenum and jejunum. They are small compound acinotubular glands, each consisting of a number of alveoli lined by short columnar epithelium and opening by a duct on the inner surface of the intestine.

The *solitary lymphatic nodules* are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. Their free surfaces are covered with rudimentary villi, except at the summits, and each nodule is surrounded by the openings of the intestinal glands. Each consists of a dense interlacing retiform tissue closely packed with lymph-corpuscles, and permeated with an abundant capillary network. The interspaces of the retiform tissue are continuous with large lymph-spaces which surround the nodule, through which

they communicate with the lacteal system. They are situated partly in the submucous tissue, partly in the mucous coat, where they form slight projections of its epithelial layer (fig. 1028).

The **aggregated lymphatic nodules** (Peyer's glands) (fig. 1028) form circular or oval patches, from twenty to thirty in number, and vary in length from 2 cm. to 10 cm.

FIG. 1029.—A transverse section through the equatorial plane of three lymphatic nodules of the rabbit.

FIG. 1030.—The myenteric plexus of the rabbit. $\times 50$.

They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, circular, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated in the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of solitary lymphatic nodules covered with columnar epithelium; the patches do not, as a rule, possess villi on their free surfaces. They are best marked in the young subject, become indistinct in middle age, and sometimes disappear altogether in advanced life. They are freely supplied with blood-vessels (fig. 1029), which form an abundant plexus around each follicle and give off fine branches permeating the lymphoid tissue in the interior of the follicle. The lymphatic plexuses are especially abundant around these patches.

Vessels and Nerves.—The jejunum and ileum are supplied by the superior mesenteric artery, the jejunal and ileal branches of which, having reached the attached border of the bowel, run between the serous and muscular coats, with frequent anastomoses, to the free border, where they also anastomose with other branches running round the opposite surface of the gut. From these vessels numerous branches are given off, which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane. The veins have a course and arrangement similar to the arteries. The lymphatics of the small intestine (lacteals) are arranged in two sets, those of the mucous membrane and those of the muscular coat. The lymphatics of the villi commence in these structures in the manner described above. They form an intricate plexus in the mucous and submucous tissue, being joined by the lymphatics from the lymph-spaces at the bases of the solitary nodules, and from this pass to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coat are situated to a great extent between the two layers of muscular fibres, where they form a close plexus; throughout their course they communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner as these into the origins of the lacteal vessels at the attached border of the gut.

FIG. 1031.—The plexus of the submucosa of the rabbit. $\times 50$.

The *nerves* of the small intestine are derived from the plexuses of *sympathetic* nerves around the superior mesenteric artery. From this source they run to the *myenteric plexus* (*Auerbach's plexus*) (fig. 1030) of nerves and ganglia, situated between the circular and longitudinal layers, from which the nervous branches are distributed to the muscular coats of the intestine. From the myenteric plexus a secondary plexus, the *plexus of the submucosa* (*Meissner's plexus*) (fig. 1031), is derived, and is formed by branches which have perforated the circular muscular layer. This plexus lies in the submucous coat of the intestine; it also contains ganglia from which the nerve-fibres pass to the muscularis mucosae and to the mucous membrane. The nerve-bundles of the submucous plexus are finer than those of the myenteric plexus.

Keith states that 'Auerbach's plexus is not composed simply of ganglionic cells and nerve-fibres; it contains numerous other cells to which Kölliker called attention, and which may be described as Kölliker's cells. These cells have small bodies which send out numerous branched processes, and differ from pure sheath cells in staining reaction and structure. It is through these cells that Auerbach's tissue is linked up with the musculature of the bowel. The nerve-fibres which former authors have described as distributed to the muscular and other coats of the bowel are probably sensory in nature. Sections of the developing bowel show that the outer and inner muscular coats are developed from a germinal layer situated between them. Auerbach's plexus represents the residue of the germinal or developmental intermediate layer. Probably the ganglionic cells may be of central origin, but the cells of Kölliker are apparently undifferentiated muscle-cells.' He states that in point of development Auerbach's plexus is similar in origin to that of the atrioventricular bundle of His, and is of opinion that they are homologous.*

THE LARGE INTESTINE (INTESTINUM CRASSUM)

The *large intestine* extends from the end of the ileum to the anus. It is about 1·5 metres long, being one-sixth of the whole extent of the intestinal canal. Its calibre is largest at its commencement at the cæcum, and gradually diminishes as far as the rectum, where there is a dilatation of considerable size just above the anal canal. It differs from the small intestine in its greater calibre, its more fixed position, its sacculated form, and in possessing certain appendages to its external coat, the *appendices epiploicae*. Further, its longitudinal muscular fibres do not form a continuous layer around the gut, but are arranged in three longitudinal bands or *taeniae*. In its course the large intestine describes an arch which surrounds the convolutions of the small intestine. It commences in the right iliac region, in a dilated part, the *cæcum*. It ascends through the right lumbar and hypochondriac regions to the under surface of the liver; here it bends (the *right colic flexure*) to the left, and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again (the *left colic flexure*), and descends through the left lumbar and iliac regions to the pelvis, where it forms a loop called the *sigmoid flexure*; from this it is continued along the lower part of the posterior wall of the pelvis to the anus. It is divided into the cæcum, the colon, the rectum, and the anal canal.

The *cæcum* (fig. 1032), the commencement of the large intestine, is the large pouch situated below the colic valve. Its closed end is directed downwards, and its open end upwards, communicating directly with the colon, of which the cæcum appears to be the beginning or head, and hence the name *caput cæcum coli* was formerly applied to it. Its size is variously estimated by different authors, but on an average it may be said to be 6·25 cm. in length and 7·5 cm. in breadth. It is situated in the right iliac fossa, above the lateral half of the inguinal ligament: it rests on the Iliacus and Psoas major, and is usually in contact with the anterior abdominal wall, but the greater omentum, and, if the cæcum be empty, some coils of small intestine, may lie in front of it. As a rule, it is entirely enveloped by peritoneum, but in about 5 per cent. of cases (Berry) the peritoneal covering is not complete, so that the upper part of the posterior surface is uncovered and is connected to the iliac fascia by connective tissue. The cæcum enjoys a considerable amount of movement, so that it may become herniated down the right inguinal canal, and has occasionally been found in an inguinal hernia on the left side. The cæcum varies in shape, but, according to Treves, it may be classified under one of four types. In early foetal life it is short, conical, and broad at the base, with its apex

* *Proceedings of the Anatomical Society of Great Britain and Ireland, January 1915.*

turned upwards and medialwards towards the ileocolic junction. It then resembles the cæcum of some monkeys, e.g. the mangabey monkey. As the foetus grows, the cæcum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination of the apex towards the ileocolic junction. This form is seen in other monkeys, e.g. the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the vermiform process, hanging from a conical projection, the cæcum. This is the infantile form, and as it persists throughout life in about 2 per cent. of cases, it is regarded by Treves as the *first* of his four types of human cæca. The cæcum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the *second* type, the

FIG. 1032.—The cæcum and vermiform process, with their arteries.

conical cæcum has become quadrate by the growing out of a saccule on either side of the anterior longitudinal band. These saccules are of equal size, and the appendix arises from between them, instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The *third* type is the normal type of man. Here the two saccules, which in the second type were uniform, have grown at unequal rates: the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downwards of the right saccule, and the original apex, with the appendix attached, is pushed over to the left towards the ileocolic junction. The three longitudinal bands still start from the base of the vermiform process, but they are now no longer equidistant from each other, because the right saccule has grown between the anterior and posterolateral bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The *fourth* type is merely an exaggerated condition of the third; the right saccule is still larger, and at the same time the left saccule has become atrophied, so that the original apex of the cæcum, with the vermiform process, is close to the ileocolic junction, and the anterior band courses medialwards to the same situation. This type is present in about 4 per cent. of cases.

The colic valve (fig. 1033).—The lower part of the ileum ends by opening into the medial and posterior part of the large intestine, at the point of junction

of the cæcum with the colon. The opening is guarded by a valve, consisting of two segments or lips, which project into the lumen of the large intestine. If the intestine has been inflated and dried, the lips are of a semilunar shape. The upper lip, nearly horizontal in direction, is attached by its convex border to the line of junction of the ileum with the colon; the lower one, which is longer and more concave, is attached to the line of junction of the ileum with the cæcum. At the ends of the aperture the two segments of the valve coalesce, and are continued as narrow membranous ridges around the canal for a short distance, forming the *frenula* of the valve. The left or anterior end of the aperture is rounded; the right or posterior is narrow and pointed. In the fresh condition, or in specimens which have been hardened *in situ*, the lips project as thick cushion-like folds into the lumen of the large gut, while the opening between them may present the appearance of a slit or may be somewhat oval in shape.

Each lip of the valve is formed by a reduplication of the mucous membrane and of the circular muscular fibres of the intestine, the longitudinal fibres

FIG. 1033.--The interior of the cæcum and the lower end of the ascending colon, showing the colic valve.

and peritoneum being continued uninterruptedly from the small to the large intestine.

The surfaces of the valve directed towards the ileum are covered with villi and present the characteristic structure of the mucous membrane of the small intestine; while those turned towards the large intestine are destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. It is generally maintained that this valve prevents reflux from the cæcum into the ileum, but in all probability it acts as a sphincter round the end of the ileum and prevents the contents of the ileum from passing too quickly into the cæcum.

The **vermiform process** or **appendix** (fig. 1032) is a long, narrow, worm-shaped tube, which starts from what was originally the apex of the cæcum, and may pass in one of several directions: upwards behind the cæcum; to the left behind the ileum and mesentery; or downwards into the lesser pelvis. It varies from 2 cm. to 20 cm. in length, the average being about 9 cm. It is retained in position by a fold of peritoneum (mesenteriole), derived from the mesentery. This fold, in the majority of cases, is more or less triangular in shape, and as a rule extends along the entire length of the tube. Between its two layers and close to its free margin lies the appendicular artery (fig. 1032). The canal of the vermiform process is small, extends throughout the whole length of the tube, and communicates with the cæcum by an orifice which is placed below and behind the ileocaecal opening. The orifice is sometimes

guarded by a semilunar valve formed by a fold of mucous membrane, but this is by no means constant.

Structure.—The coats of the vermiform process are the same as those of the intestine: serous, muscular, submucous, and mucous. The *serous* coat forms a complete investment for the tube, except along the narrow line of attachment of its mesenteriole in its proximal two-thirds. The *longitudinal muscular fibres* do not form three bands as in the greater part of the large intestine, but invest the whole organ, except at one or two points where both the longitudinal and circular layers are deficient, so that the peritoneal and submucous coats are contiguous over small areas. The *circular muscular fibres* form a thicker layer than the longitudinal fibres, and are separated from them by a small amount of connective tissue. The *submucous* coat is well marked, and contains a large number of masses of lymphoid tissue which cause the mucous membrane to bulge into the lumen and so render the latter of small size and irregular shape. The *mucous membrane* is lined by columnar epithelium and resembles that of the rest of the large intestine, but the intestinal glands are fewer in number (fig. 1034).

The colon is divided into four parts: the ascending, transverse, descending, and sigmoid.

FIG. 1034.—Transverse section of human vermiform process. $\times 20$.

The **ascending colon**, about 15 cm. long, is smaller in calibre than the cæcum. It begins at the cæcum, and ascends to the under surface of the right lobe of the liver, where it is lodged in a shallow depression, the colic impression; here it bends abruptly forwards and to the left, forming the *right colic (hepatic) flexure* (fig. 1021). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Iliacus, Quadratus lumborum, aponeurotic origin of Transversus abdominis, and with the front of the lower and lateral part of the right kidney. Sometimes the peritoneum completely invests it, and forms a distinct but narrow mesocolon.* It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

* Traves, after a careful examination of one hundred subjects, found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colotomy a mesocolon may be expected upon the left side in 36 per cent. of all cases, and on the right in 26 per cent.—*The Anatomy of the Intestinal Canal and Peritoneum in Man*, 1885, p. 55.

The **transverse colon**, about 50 cm. long, passes with a downward convexity from the right hypochondriac region across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves sharply backwards on itself beneath the lower end of the spleen, forming the *left colic (splenic) flexure*. In its course it describes an arch, the concavity of which is usually directed backwards and a little upwards; towards its splenic end there is often an abrupt U-shaped curve which may descend lower than the main curve. It is almost completely invested by peritoneum, and is connected to the anterior border of the pancreas by the *transverse mesocolon*. It is in relation, by its upper surface, with the liver and gall-bladder, the greater curvature of the stomach, and the lower end

FIG. 1035.—The descending colon, sigmoid colon, and rectum, seen from the front, after the removal of the pubic bones and bladder.

of the spleen; by its under surface, with the small intestine; by its anterior surface with the anterior layers of the greater omentum and the abdominal parietes; its posterior surface is in relation from right to left with the descending portion of the duodenum, the head of the pancreas, and some of the convolutions of the jejunum and ileum.

The *left colic or splenic flexure* (fig. 1021) is situated at the junction of the transverse and descending parts of the colon, and is in relation with the lower end of the spleen and the tail of the pancreas; the flexure is so acute that the end of the transverse colon usually lies in contact with the front of the descending colon. The left colic flexure lies at a higher level than, and on a plane posterior to, the right, and is attached to the Diaphragm, opposite the tenth and eleventh ribs, by a peritoneal fold, named the *phrenicocolic ligament*, which assists in supporting the lower end of the spleen (p. 1096).

The **descending colon** passes downwards through the left hypochondriac and lumbar regions and in front of the lower part of the left kidney. At the lower end of the kidney it turns medialwards towards the lateral border of the Psoas major, and descends, in the angle between Psoas major and Quadratus lumborum,

to the crest of the ilium ; it then curves downwards and medialwards in front of the Iliacus and Psoas major, and ends in the sigmoid colon at the superior aperture of the lesser pelvis.* The peritoneum covers its anterior surface and sides, while its posterior surface is connected by areolar tissue with the lower and lateral part of the left kidney, the aponeurotic origin of the Transversus abdominis, the Quadratus lumborum, the Iliacus and the

FIG. 1036.—The posterior aspect of the rectum exposed by removing the lower part of the sacrum and the coccyx.

Psoas major (figs. 1021 and 1035). It is smaller in calibre, more deeply placed, and more frequently covered with peritoneum on its posterior surface, than the ascending colon (Treves). In front of it are some coils of small intestine.

The sigmoid colon (sometimes called the *pelvic colon*) (fig. 1035) forms a loop which averages about 20 cm. in length, and normally lies within the pelvis. It begins at the superior aperture of the lesser pelvis, where it is continuous with the descending colon, and the loop consists of three parts: the first descends in contact with the left pelvic wall; the second crosses the pelvic cavity, between the rectum and bladder in the male, and the rectum and uterus

*That portion of the descending colon which extends from the crest of the ilium to the superior aperture of the lesser pelvis is sometimes named the *Siac colon*.

in the female, and may come into contact with the right pelvic wall; the third arches backwards and reaches the middle line at the level of the third piece of the sacrum, where it bends downwards and ends in the rectum. The sigmoid colon is completely surrounded by peritoneum, which forms a mesentery, the *sigmoid mesocolon* (p. 1096); this diminishes in length from the centre towards the ends of the loop, where it disappears, so that the loop is fixed at its junctions with the descending colon and rectum, but enjoys a considerable range of movement in its central portion. Behind the sigmoid colon are the external iliac vessels, the left Piriformis, and left sacral plexus of nerves; in front of it are some coils of the small intestine which separate it from the bladder in the male, and from the uterus in the female.

The position and shape of the sigmoid colon vary very much, and depend on (a) its length; (b) the length and freedom of its mesocolon; (c) the condition of distension; when distended it rises out of the pelvis into the abdominal cavity, and when empty it sinks again into the pelvis; (d) the condition of the rectum and bladder (and the uterus, in the female); when these organs are distended the sigmoid colon tends to rise, and conversely.

The **rectum** (figs. 1035, 1036) is continuous above with the sigmoid colon, whilst below it ends in the anal canal. From its origin at the level of the third sacral vertebra it passes downwards, lying in the sacrococcygeal curve, and extends for about 2.5 cm. in front of, and a little below, the tip of the coccyx, as far as the apex of the prostate. It then bends sharply backwards into the anal canal. It therefore presents two anteroposterior flexures: an upper or *sacral flexure* with its convexity backwards, and a lower or *perineal flexure*, with its convexity forwards. Two lateral curves are also described, one convex to the right opposite the junction of the third and fourth sacral vertebrae, and the other to the left, opposite the sacrococcygeal articulation; they are, however, of little importance. The rectum is about 12 cm. long, and at its commencement its calibre is similar to that of the sigmoid colon, but near its termination it is dilated to form the *rectal ampulla*. It has no sacculations comparable to those of the colon, but when the lower part of it is contracted its mucous membrane is thrown into a number of folds, which are longitudinal in direction and are effaced by the distension of the gut. Besides these there are certain permanent *transverse folds* (plicæ transversales recti), of a semilunar shape, known as *Houston's*

FIG. 1037.—A coronal section of the rectum and anal canal.

valves (fig. 1037). There are usually three, but sometimes a fourth or fifth is found, and occasionally only two are present. One is situated near the commencement of the rectum, on the right side; a second extends inwards from the left side of the tube, opposite the middle of the sacrum; a third, the largest and most constant, projects backwards from the fore part of the rectum, opposite the fundus of the urinary bladder. When a fourth is present, it is situated nearly 2.5 cm. above the anus on the left and posterior wall of the tube. These folds are about 12 mm. in width and contain some of the circular fibres of the gut. In the empty state of the intestines they overlap each other, as Houston remarks, so effectually as to require considerable manœuvring to conduct a bougie or the finger along the canal. Their use seems to be to support the weight of faecal matter, and prevent its urging

wards the anus, where its presence always excites a sensation demanding discharge.*

The peritoneum is related to the upper two-thirds of the rectum, covering at first its front and sides, but lower down its front only; from the latter it is reflected on to the seminal vesicles in the male and the posterior vaginal wall in the female.

The level at which the peritoneum is reflected from the rectum on to the viscus in front of it is higher in the male than in the female. In the former the height of the rectovesical excavation is about 7.5 c.m. (i.e. the height to which an ordinary index finger can reach) from the anus. In the female the height of the recto-uterine excavation is about 5.5 cm. from the anal orifice. The rectum is surrounded by a dense tube of fascia derived from the fascia endopelvina, but fused behind with the fascia covering the sacrum and coccyx. The fascial tube is loosely attached to the rectal wall by areolar tissue, in order to allow of distension of the viscus.

Relations of the rectum.—

The upper part of the rectum is in relation, *behind*, with the superior hæmorrhoidal vessels, the left Piri-formis and the left sacral plexus of nerves, which separate it from the pelvic surfaces of the sacral vertebræ; its lower part lies on the sacrum, coccyx, and Levatores ani; it is attached to the sacrum along the lines of the sacral foramina by connective tissue which surrounds the sacral nerves and branches of the superior hæmorrhoidal vessels passing to the bowel. *In front* of its upper part, in the male, is the rectovesical excavation;

in the female, the recto-uterine excavation of the peritoneum. In either sex the excavation contains some convolutions of the small intestine, and frequently the sigmoid colon. Below the rectovesical excavation, its anterior surface is in relation in the male with the triangular portion of the fundus of the bladder, the vesiculæ seminales, and ductus deferentes, and more anteriorly with the posterior surface of the prostate; in the female, with the posterior wall of the vagina.

The anal canal (*pars analis recti*) (fig. 1038) begins at the level of the apex of the prostate, is directed downwards and backwards, and ends at the anus. It forms an angle with the lower part of the rectum, and measures about 2.5 cm. in length. It has no peritoneal covering, but is invested by the Sphincter ani internus, supported by the Levatores ani, and surrounded at its termination by the Sphincter ani externus. In the empty condition it presents the appearance of an anteroposterior longitudinal slit. Behind it, is a mass of muscular and fibrous tissue, the *anococcygeal body* (Symington); in front of it, in the male, but separated from it by connective tissue, are the membranous portion and bulb of the urethra, and the fascia of the urogenital diaphragm; and in the female it is separated from the lower end of the vagina by a mass of muscular and fibrous tissue, named the *perineal body*.

* Paterson (The Form of the Rectum, *Journal of Anatomy and Physiology*, vol. xlii.) utilises the third fold for the purpose of dividing the rectum into an upper and a lower portion; he considers the latter 'to be just as much a duct as the narrower anal canal below,' and maintains that, under normal conditions, it does not contain faeces except during the act of defecation.

FIG. 1038.—A coronal section through the anal canal. (Symington.)

The upper half of the anal canal is lined by mucous membrane which presents from six to ten vertical folds known as the *rectal columns* (*Morgagni*) (fig. 1037). They are produced by an infolding of the mucous membrane and some of the longitudinal muscular tissue, and are separated from one another by furrows which end below in small crescentic valve-like folds, termed *anal valves*; these valves join together the lower ends of the rectal columns, and outside each valve is a small pouch or *rectal sinus*.

The lower half of the anal canal is lined by skin which exhibits a series of folds extending upwards from the anus towards the rectal columns. The junction of the skin and mucous membrane is indicated by a white line which is somewhat wavy owing to the interlocking of the cutaneous and mucous folds' (Symington).

The **anus** or **anal orifice** is the lower aperture of the anal canal, and is situated in front of the apex of the coccyx in the cleft between the buttocks. The skin surrounding it is thrown into a series of folds which converge towards the orifice and are continued upwards into the lower part of the anal canal.

Structure of the colon--The large intestine has four coats: serous, muscular, areolar, and mucous.

The *serous coat* is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The cæcum is usually completely covered by the serous membrane, but in about 5 per cent. of cases the upper part of the posterior surface is uncovered. The ascending and descending parts of the colon are usually covered only in front and at the sides: a variable amount of the posterior surface is uncovered.* The transverse colon is invested with the exception of (a) the posterior surface of that part which lies in front of the duodenum and the head of the pancreas, and (b) along the lines of attachment of the greater omentum and transverse mesocolon. The sigmoid colon is entirely surrounded. The upper part of the rectum is covered on its anterior surface and sides; the middle part on its anterior surface only; while the lower 5 cm. of the rectum and the anal canal are devoid of any serous covering. In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called *appendices epiploicae*. They are most numerous on the transverse colon.

The *muscular coat* consists of an external longitudinal, and an internal circular layer of non-striped muscular fibres.

The *longitudinal fibres* do not form a continuous layer over the whole surface of the large intestine. In the cæcum and colon they are especially collected into three flat longitudinal bands (*tæniæ coli*), each of about 12 mm. in width; one, the posterior (*tænia mesocolica*), is placed along the attached border of the intestine; the anterior, the largest (*tænia omentalis*), corresponds, along the arch of the colon, with the attachment of the greater omentum, but is in front in the ascending, descending, and sigmoid parts of the colon; the third (*tænia libera*) is found on the medial side of the ascending and descending parts of the colon, and on the under aspect of the transverse colon. These bands are shorter than the other coat of the intestine, and serve to produce the sacculi which are characteristic of the cæcum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. In the sigmoid colon the longitudinal fibres become more scattered; and round the rectum they spread out and form a layer, which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces, where it forms two bands. In addition, two fasciculi of plain muscular tissue arise from the front of the second and third coccygeal vertebrae, and pass downwards and forwards to blend with the longitudinal muscular fibres on the posterior wall of the anal canal. These are known as the *Rectococcygeal muscles*.

The *circular fibres* form a thin layer over the cæcum and colon, being especially accumulated in the intervals between the sacculi: in the rectum they form a thick layer, and in the anal canal they become numerous, and constitute the *Sphincter ani internus*.

The *areolar coat* connects the muscular and mucous layers closely together.

The *mucous membrane*, in the cæcum and colon, is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond with the intervals between the sacculi. In the rectum it is thicker, of a darker colour, more vascular, and connected loosely with the muscular coat.

As in the small intestine, the mucous membrane (fig. 1039) consists of a muscular layer, the *muscularis mucosæ*: a quantity of retiform tissue in which the vessels ramify; a basement membrane, and an epithelium which is of the columnar variety and resembles the epithelium found in the small intestine. The mucous membrane of the large intestine presents for examination glands and solitary lymphatic nodules.

The *glands* of the great intestine are minute tubular prolongations of the mucous membrane arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine;

* Footnote, p. 1117.

and they open by minute rounded orifices upon the surface, giving it a cribriform appearance. Each gland is lined by short columnar epithelium, the majority of the cells being goblet cells.

The *solitary lymphatic nodules* (fig. 1039) of the large intestine are most abundant in the cæcum and vermiform process, but are irregularly scattered also over the rest of the large intestine. They are similar to those of the small intestine.

Vessels and Nerves.—The *arteries* supplying the colon are derived from the colic and sigmoid branches of the mesenteric arteries. They give off large branches, which ramify between and supply the muscular coats, and after dividing into small vessels in the sub-mucous tissue, pass to the mucous membrane. The rectum is supplied by the superior hæmorrhoidal branch of the inferior mesenteric, and the anal canal by the middle hæmorrhoidal from the hypogastric, and the inferior hæmorrhoidal from the internal pudendal artery. The superior hæmorrhoidal, the continuation of the superior mesenteric, divides into two branches, which run down either side of the rectum to within about 12·5 cm. of the anus; they here divide into a number of branches, which pierce the muscular coat and descend between it and the mucous membrane in the rectal columns as far as the

FIG. 1039.—A section through the mucous membrane of the human rectum. $\times 60$. (Sobotta.)

Sphincter ani internus, where they anastomose with the other hæmorrhoidal arteries and form a series of loops around the anus. The *veins* of the rectum commence in a plexus of vessels which surrounds the anal canal. In the vessels forming this plexus are small saccular dilatations just within the margin of the anus; from the plexus about six vessels of considerable size are given off. These ascend between the muscular and mucous coats for about 12·5 cm., running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the superior hæmorrhoidal vein. This arrangement is termed the *hæmorrhoidal plexus*; it communicates with the tributaries of the middle and inferior hæmorrhoidal veins, at its commencement, and thus a communication is established between the systemic and portal circulations. The *nerves* are derived from the sympathetic plexuses around the branches of the superior and inferior mesenteric arteries. They are distributed in a similar way to those found in the small intestine.

The *lymphatics* of the large intestine are described on p. 731.

Applied Anatomy.—The small intestine is much exposed to injury, but, in consequence of its elasticity and the ease with which one coil glides over another, it is not so frequently ruptured as would otherwise be the case. Any part of it may be ruptured, but probably the most common situation is the horizontal portion of the duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the intestine is struck by a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, it is said, 6 mm. in length, no extravasation of the contents of the bowel takes place: the mucous membrane becomes everted and plugs the little opening. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways; they may be old peritoneal adhesions from

previous attacks of peritonitis; or an adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or it may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicæ, or an adherent vermiform process or uterine tube. Intussusception, most commonly an invagination of the small intestine into the large, may take place; it may attain great size, and it is possible in these cases to find the colic valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (*volvulus*) may also lead to intestinal obstruction.

Resection of a portion of the intestine may be required in cases of gangrene; for the removal of new-growth in the bowel; in dealing with artificial anus; and in cases of rupture. The operation is termed *enterectomy*, and is performed as follows: the abdomen having been opened and the amount of bowel requiring removal having been determined upon, the intestine must be clamped on either side of this portion in order to prevent the escape of any of its contents during the operation. The portion of the bowel is then separated above and below by means of scissors. If the portion resected is small, it may be simply removed from the mesentery at its attachment, and the bleeding vessels tied; but if it be large it will be necessary to take away a triangular piece of the mesentery, and, having secured the vessels, suture the cut edges of this structure together. In doing this, care must be taken not to leave any intestine projecting beyond the line of the section of the mesentery, as gangrene is very likely to occur in the projecting part if this is done. The surgeon then proceeds to unite the cut ends of the bowel together by end-to-end anastomosis. There are many ways of doing this, but they may be divided into two classes, one where the anastomosis is made by means of some mechanical appliance, such as Murphy's button, or one of the forms of decalcified bone bobbin; and the other, where the operation is performed by suturing the ends of the bowel in such a manner that the peritoneum covering the two divided ends is brought into contact, so that speedy union may ensue.

The vermiform process is very liable to become inflamed, because it contains a relatively large amount of lymphoid tissue which is prone to bacterial infection. In many cases the inflammation is set up by the impaction in it of a solid mass of feces or a foreign body, or by the inspissation of its mucous secretion in catarrhal conditions. The inflammation may result in ulceration and perforation, or if very acute in gangrene of the process. These conditions generally require immediate operative interference, and in chronic cases with recurring attacks of inflammation it is always advisable to remove this diverticulum of the bowel. In making the abdominal wall for this operation, the muscles should be split in the direction of their fibres, rather than cut across, in order to prevent subsequent weakening of the abdominal parietes and the occurrence of a ventral hernia. After the process has been removed it is better to suture the planes of the abdominal wall separately.

In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved it is usually the cæcum, and this may occur even on the left side. In some few cases the vermiform process has been the part implicated in strangulated hernia.

Chronic ulcer of the duodenum is sometimes met with, probably produced by the same causes as chronic ulcer of the stomach. It may perforate and set up a rapidly fatal peritonitis, or it may open into one of the large duodenal vessels and cause death from hæmorrhage. An acute ulcer sometimes, but rarely, follows extensive burns of the skin.

The calibre of the large intestine gradually diminishes from the cæcum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid colon with the rectum. At or a little below this point stricture most commonly occurs, and diminishes in frequency as one proceeds upwards to the cæcum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the right and left colic flexures, which are more deeply placed; the distension is most obvious in the flanks and on the front of the abdomen just above the umbilicus. The cæcum, however, is the portion of the bowel which becomes most distended. It may assume enormous dimensions, and may give way from the distension, leading to rapidly fatal peritonitis. The right colic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the duodenum or colon, and gall-stones may find their way into either, and may become impacted or may be discharged per anum. The mobility of the sigmoid colon renders it more liable to become the seat of a *volvulus* or twist than any other part of the intestine. This generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesocolon is elongated. This portion of the bowel, being loaded with feces, falls over the part below, and so gives rise to the twist.

Hernia.—The two chief sites at which external hernia may take place are the inguinal region and the femoral canal. The description of the inguinal canal and its relations will be found on p. 465 and that of the femoral canal on p. 664. Some points in regard to the disposition of the peritoneum in these regions may, however, be recapitulated here.

Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into five folds, with inter-

vening depressions, by more or less prominent bands which converge to the umbilicus (fig. 1000). The middle umbilical ligament, situated in the middle line, is covered by a fold of peritoneum known as the *middle umbilical fold*. On either side of this a fold of peritoneum round the obliterated umbilical artery forms the *lateral umbilical fold*. To either side of these three cords is the inferior epigastric artery covered by the *epigastric fold*. Between these raised folds are depressions constituting the so-called *foveæ*. The most medial, between the middle and lateral umbilical folds, is known as the *supravesical fovea*. The intermediate one is situated medially to the epigastric fold, and is termed the *medial inguinal fovea*. The third is lateral to the epigastric fold, and is known as the *lateral inguinal fovea*. Occasionally the inferior epigastric artery corresponds in position to the obliterated hypogastric artery, and then there is but one fold on either side of the middle line. In the usual position of the parts, the floor of the lateral inguinal fovea corresponds to the abdominal inguinal ring, and into this fovea an oblique inguinal hernia descends. Medially to the epigastric fold are the medial inguinal and the supravesical foveæ, and through either of these a direct hernia may descend. The whole of the space between the inferior epigastric artery, the margin of the Rectus abdominis, and the inguinal ligament, is known as Hesselbach's triangle. Below the level of the inguinal ligament is a small depression corresponding to the position of the femoral ring. It is known as the *femoral fovea*, and into it a femoral hernia descends.

FIG. 1040.—The varieties of oblique inguinal hernia.

Inguinal hernia.—Inguinal hernia is that form of protrusion which makes its way through the abdominal wall in the inguinal region. There are two principal varieties: lateral or oblique, and medial or direct.

In *oblique inguinal hernia* the intestine escapes from the abdominal cavity at the abdominal inguinal ring, pushing before it a pouch of peritoneum which forms the hernial sac. As it enters the inguinal canal it receives an investment from the extraperitoneal tissue and is enclosed in the infundibuliform fascia. In passing along the inguinal canal it displaces upwards the arched fibres of the Transversus and Obliquus internus, and receives a covering of Cremaster muscle and cremasteric fascia. It then passes along the front of the spermatic cord and escapes from the inguinal canal at the subcutaneous inguinal ring, becoming invested by intercrural fascia. Lastly it descends into the scrotum, receiving coverings from the superficial fascia and the skin.

The seat of stricture in oblique inguinal hernia is at either the abdominal or the subcutaneous inguinal ring; most frequently at the former situation. If it is situated at the subcutaneous ring, the division of a few fibres at one point of the circumference is all that is necessary for the replacement of the hernia. If at the abdominal ring, it is necessary to divide the aponeurosis of the Obliquus externus so as to lay open the inguinal canal; in dividing the aponeurosis the incision should be directed parallel to the inguinal ligament, and the constriction at the abdominal ring should then be divided directly upwards.

When the intestine passes along the inguinal canal and escapes from the subcutaneous ring into the scrotum, it is called a *scrotal hernia*. If the intestine does not pass into the scrotum, but merely bulges through the subcutaneous ring, it is called a *hydrocele*.

The great majority of varieties of oblique inguinal hernia depend upon congenital defects in the saccus vaginalis, the pouch of peritoneum which precedes the descent of the testis. Normally this pouch is closed before birth, closure commencing at two points, viz. at the abdominal inguinal ring and at the top of the epididymis, and gradually extending until the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process, variations in the relation of the hernial protrusion to the testis and tunica vaginalis are produced; these constitute distinct varieties of inguinal hernia, viz. the hernia of the funicular process and the complete congenital variety.

Where the sacculus vaginalis remains patent throughout, the cavity of the tunica vaginalis communicates directly with that of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testis. Though this form of hernia is termed *complete congenital* (fig. 1040), the term does not imply that the hernia existed at birth, but merely that a condition is present which may allow of the descent of the hernia at any moment. As a matter of fact, congenital herniæ frequently do not appear till adult life.

Where the processus vaginalis is occluded at the lower point only, i.e. just above the testis, the intestine descends into the pouch of peritoneum as far as the testis, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch. This is known as *hernia into the funicular process or incomplete congenital hernia* (fig. 1040); it differs from the former in that instead of enveloping the testis it lies above it.

In *direct inguinal hernia* the protrusion makes its way through some part of Hesselbach's triangle, either through (a) the lateral part, where only extraperitoneal tissue and transversalis fascia intervene between the peritoneum and the aponeurosis of the Obliquus externus; or through (b) the inguinal aponeurotic falx which stretches across the medial two-thirds of the triangle between the artery and the middle line. In the former the hernial protrusion escapes from the abdomen on the lateral side of the inguinal falx, pushes before it the peritoneum, extraperitoneal tissue and transversalis fascia, and enters the inguinal canal. It passes along nearly the whole length of the canal and finally emerges from the subcutaneous ring, receiving an investment from the intercrural fascia. The coverings of this form of hernia are similar to those of the oblique form, except that a portion derived from the general layer of transversalis fascia replaces the infundibuliform fascia.

In the second form, which is the more frequent, the hernia is either forced through the fibres of the inguinal falx, or the falx is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the subcutaneous ring, lying on the medial side of the cord, and receives additional coverings from the intercrural fascia, the superficial fascia and the integument. The coverings of this form therefore differ from those of the oblique form in that the inguinal falx is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion of the general layer of the transversalis fascia.

The seat of stricture in both varieties of direct hernia is usually found either at the neck of the sac or at the subcutaneous ring. In that form which perforates the inguinal falx it may occur at the edges of the fissure through which the gut passes. In all cases of inguinal hernia, whether direct or oblique, it is proper to divide the stricture directly upwards; by cutting in this direction the incision is made parallel to the inferior epigastric artery—laterally to it in the oblique variety, medially to it in the direct form of hernia; all chance of wounding the vessel thus avoided. Direct inguinal hernia is of much less frequent occurrence than oblique, and is found more often in men than in women. The main differences in position between it and the oblique form are: (a) it is placed over the os pubis and not in the course of the inguinal canal; (b) the inferior epigastric artery runs on the lateral or iliac side of the neck of the sac; and (c) the spermatic cord lies along its lateral and posterior sides, not directly behind it as in oblique inguinal hernia. A direct hernia is always of the acquired variety, whereas the oblique form is most commonly due to non-obliteration of part or the whole of the peritoneal pouch which accompanies the testis in its descent, and the sac is therefore most often congenital although the contents may not descend till later in life.

Femoral hernia.—In femoral hernia the protrusion of the intestine takes place through the femoral ring. As already described (p. 654), this ring is closed by the femoral septum, a partition of modified extraperitoneal tissue; it is therefore a weak spot in the abdominal wall, and especially in the female, where the ring is larger, and where profound changes are produced in the tissues of the abdomen by pregnancy. Femoral hernia is therefore more common in women than in men.

When a portion of intestine is forced through the femoral ring, it carries before it a pouch of peritoneum, which forms the hernial sac. It receives an investment from the extraperitoneal tissue or femoral septum, and descends along the femoral canal, or inner compartment of the sheath of the femoral vessels, as far as the fossa ovalis; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the latter, and its close contact with the vessels, and also the close attachment of the superficial fascia and femoral sheath to the lower part of the circumference of the fossa ovalis. The tumour is consequently directed forwards, pushing before it the fascia cribrosa, and then curves upwards over the inguinal ligament and the lower part of the aponeurosis of the Obliquus externus, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts, but when it escapes from the fossa ovalis into the loose areolar tissue of the groin it becomes considerably enlarged. The direction taken by a femoral hernia is at first downwards, then forwards and upwards; in the application of taxis for the reduction of a femoral hernia, therefore, pressure should be directed in the reverse order.

The coverings of a femoral hernia from within outwards are: peritoneum, femoral septum, femoral sheath, fascia cribrosa, superficial fascia, and integument. Sir Astley Cooper has described an investment for femoral hernia under the name of *fascia propria*, lying immediately external to the peritoneal sac but frequently separated from it by some adipose tissue. Surgically it is important to remember the frequent existence of this layer on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained extraperitoneal fat for omentum, as there is often a great excess of subperitoneal fatty tissue enclosed in the 'fascia propria.' In many cases it resembles a fatty tumour, but on further dissection the true hernial sac will be found in the centre of the mass of fat. The fascia propria is merely a modified femoral septum which has been thickened to form a membranous sheet by the pressure of the hernia.

When the intestine descends along the femoral canal only as far as the fossa ovalis the condition is known as *incomplete* femoral hernia, in contradistinction to the *complete* hernia when it has passed through the fossa ovalis. The small size of the protrusion in the incomplete form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia would be from without inwards: integument, superficial fascia, superior cornu of falciform margin of the fossa ovalis, femoral sheath, femoral septum, and peritoneum.

The seat of stricture of a femoral hernia varies: it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it is at the point of junction of the falciform margin of the fossa ovalis with the free edge of the lacunar ligament; or it may be at the margin of the fossa ovalis. The stricture should in every case be divided in a direction upwards and medialwards for a distance of about 4 mm. to 6 mm. All vessels or other structures of importance in relation to the neck of the sac will thus be avoided.

The pubic tubercle forms an important landmark in serving to differentiate the inguinal from the femoral variety of hernia. The inguinal protrusion is above and medial to the tubercle, while the femoral is below and lateral to it.

There are several details of practical interest in connexion with the mesentery which merit notice. 1. The depth of the mesentery—that is to say, the distance from its parietal to its intestinal attachment—is normally less than 20 cm., generally nearer 15 cm.; but under certain abnormal conditions it may become elongated, and this would appear to favour the occurrence of hernia of the intestine. 2. Not only may the depth of the mesentery be increased, but its point of attachment to the posterior abdominal wall may yield, and descend over the lumbar vertebrae. This condition, which is known under the name of *enteroptosis*, usually occurs in women who have borne many children, and is attended with general relaxation of the abdominal parietes. It produces a characteristic appearance, the abdomen being prominent and pendulous below, while above, it is flattened and constricted. 3. Holes are sometimes present in the mesentery, and these may be congenital, or may be the result of injury. They are of practical importance, since a knuckle of intestine may become herniated into one of them, causing acute strangulation. 4. The lymph-glands contained between the two layers of the mesentery are frequently the seat of tuberculous deposit, especially in children.

Colon.—The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum as soon as the disease is recognised, in the hope that the symptoms may be relieved by removing the irritation produced by the passage of fecal matter over the diseased surface. The operation of *colostomy* may be performed either in the iliac or lumbar region; but *iliac colostomy* has in the present day entirely superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process of the mesocolon can be formed, which prevents any fecal matter finding its way past the artificial anus, and the greater ease in maintaining cleanliness. The sigmoid colon being entirely surrounded by peritoneum, a coil can be drawn out of the wound and opened, leaving the attachment of the mesocolon to form a spur, much as it does in an artificial anus caused by sloughing of the intestine after a strangulated hernia, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision 5 cm. to 7 cm. long through the outermost fibres of the left Rectus abdominis, opposite the anterior superior iliac spine. The peritoneum is opened; the sigmoid colon is now sought, pulled out of the wound, and fixed by passing a glass rod beneath it, or by suturing the mesocolon close to the gut to the abdominal wall. Later, the protruding coil of intestine is opened, and finally, when firm adhesions have formed, it is cut completely across.

Rectum.—The surgical anatomy of the rectum is of considerable importance. There may be congenital malformations due to arrest of, or imperfection in, development. Thus, there may be no proctodæal invagination (see p. 139), and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the proctodæal invagination may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fetal life exists between the two.

The mucous membrane of the rectum is thick and but loosely connected to the muscular coat beneath, and thus favours prolapse, especially in children. The vessels of the rectum are arranged, as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favours varicosity. Moreover, the veins, after running upwards in a longitudinal direction for about 12.5 cm. in the submucous tissue, pierce the muscular coats, and are liable to become constricted at this spot by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened feces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani externus is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing, and causes it to become a fistula. Also the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the bowel are of importance in connexion with the operation of removal of the rectum for malignant disease. This membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface, to become reflected, in the male on to the posterior wall of the bladder, forming the rectovesical excavation, and in the female on to the posterior wall of the vagina, forming the recto-uterine excavation. The rectovesical excavation extends to within 7.5 cm. from the anus. Within recent years much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily to be opened. For cases of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the perineum, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the last piece of the sacrum to the anus. The coccyx is removed, and if necessary a small piece of the sacrum, and the edges of the wound being now forcibly drawn outwards, a considerable length of the rectum is brought into view, and the diseased portion is removed.

The loose connective tissue round the rectum, above the Levator ani, is occasionally the site of an abscess, the active focus of which, however, may be located elsewhere. This form of abscess may be described as the *superior pelvirectal*; it is placed above the pelvic diaphragm but beneath the peritoneum. The acute variety is generally due to ulceration or perforation of the bowel (possibly produced by a foreign body) above the level of attachment of the Levator ani. The abscess may also occur above a stricture (simple or malignant) of the rectum; occasionally it arises from suppuration around the prostate, and more rarely follows abscess of the vesiculæ seminales. Chronic abscesses also appear in the same region either from caries of the anterior surface of the sacrum or from caseation of the presacral lymph-glands, whilst in other cases an abscess finds its way down into the pelvis from disease of the anterior surfaces of the bodies of the lumbar vertebrae. For abscess in the ischio-rectal fossa, see p. 472.

THE PANCREAS

The **pancreas** is a compound racemose gland, analogous in its structure to the salivary glands, but softer, and less compactly arranged. It is irregularly prismatic in shape, and from 12 cm. to 15 cm. long. Its right extremity, being broad, is called the *head*, and is connected to the main portion, or *body*, of the organ by a slightly constricted part, the *neck*; while its left extremity gradually tapers to form the *tail*. It is placed across the posterior wall of the abdomen, at the back of the epigastrium and left hypochondriac regions.

Relations (figs. 1041 to 1043).—The **head**, flattened from before backwards, is lodged within the curve of the duodenum. Its upper border is overlapped by the superior part of the duodenum; the other borders are grooved to receive the adjacent margin of the duodenum which they there overlap in front and behind to a variable extent. The angle of junction of the lower and left lateral borders forms a prolongation, termed the *uncinate process* which projects to the left behind the superior mesenteric vessels. In or near the groove between the duodenum and the right lateral and lower borders anteriorly are the anastomosing superior and inferior pancreaticoduodenal arteries; the common bile-duct descends behind the head, close to its right border.

Anterior surface.—The upper part of the *right half* of this surface of the head is in contact with the transverse colon, only areolar tissue intervening. The lower part of the right half is covered by peritoneum continuous with the inferior layer of the transverse mesocolon, and is in contact with the coils

of the small intestine. The *neck* springs from the upper part of the *left half*, the right limit of the neck being marked by a groove for the gastroduodenal

FIG. 1041.—A transverse section through the abdomen at the level of the middle of the first lumbar vertebra. (Braune.)

FIG. 1042.—The duodenum and pancreas.

artery. The lower part forms the uncinat process which, as already stated, is crossed by the superior mesenteric vessels. The superior mesenteric vein

runs upwards on the right side of the artery, and, behind the neck, joins with the lienal vein to form the portal vein.

Posterior surface.—The posterior surface of the head is in relation with the inferior vena cava, the renal veins, the right crus of the Diaphragm, and the aorta. The common bile duct either lies in a groove on the posterior surface of the head of the pancreas or in a canal in its substance (McConnell *).

The neck is about 2 cm. long, and is confluent below and to the right with the anterior surface of the head; it extends upwards and to the left, and merges imperceptibly with the body. It is a somewhat ridge-like part of the pancreas, accentuated by two vascular depressions; below and to the left is the deep notch containing the superior mesenteric vessels, while above and to the right is a groove in which the lower end of the gastroduodenal

FIG. 1043.—The pancreas and duodenum. From behind.
(From a model by His.)

artery and its continuation, the superior pancreaticoduodenal artery, are lodged. Its anterior surface supports the pylorus; its posterior surface is in relation with the commencement of the portal vein.

The body is somewhat prismatic in shape, and has three surfaces: anterior, posterior, and inferior.

The anterior surface is somewhat concave, and is directed forwards and upwards; it is separated from the stomach by the omental bursa.

The posterior surface is devoid of peritoneum, and is in contact with the aorta, the lienal vein, the left kidney and its vessels, the left suprarenal gland, the origin of the superior mesenteric artery, and the crura of the Diaphragm.

The inferior surface is narrow on the right but broader on the left, and is covered by peritoneum; it lies upon the duodenojejunal flexure and on some coils of the jejunum; its left extremity rests on the left colic flexure.

The superior border is blunt and flat to the right; narrow and sharp to the left, near the tail. It is in relation with the celiac artery, from which the hepatic artery courses to the right just above the gland, while the lienal artery runs towards the left in a groove along this border. A process, the *tuber omentale*, usually projects from the right end of the superior border above the level of the lesser curvature of the stomach, and is in contact with the hinder aspect of the lesser omentum.

The *anterior border* separates the anterior from the inferior surface, and along this border the two layers of the transverse mesocolon diverge from one another: one passing upwards over the anterior surface, the other backwards over the inferior surface.

The *inferior border* separates the posterior from the inferior surface; the superior mesenteric vessels emerge under its right extremity.

The *tail* is narrow; it projects upwards behind the splenic vessels, coming into contact with the inferior part of the gastric surface of the spleen.

Birmingham described the body of the pancreas as projecting forwards as a prominent ridge into the abdominal cavity and forming part of a bed or shelf on which the stomach lies. 'The portion of the pancreas to the left of the middle line has a very considerable anteroposterior thickness; as a result

FIG. 1044.—The pancreatic duct.

the anterior surface is of considerable extent; it looks strongly upwards, and forms a large and important part of the shelf. As the pancreas extends to the left towards the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney forms an extension inwards and backwards of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upwards and backwards into the concave gastric surface of the spleen, which completes the bed behind and to the left, and, running upwards, forms a partial cap for the wide end of the stomach.*

The **pancreatic duct** (ductus Wirsungi) traverses the pancreas from left to right, lying nearer its posterior than its anterior surface (fig. 1044). It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck, and turning downwards, backwards, and to the right, comes into relation with the common bile-duct, which lies to its right side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats of the duodenum, and ends by an orifice common

* *Journal of Anatomy and Physiology*, vol. xxxi. pt. 1, p. 102.

to it and the common bile-duct upon the summit of the duodenal papilla, situated at the medial side of the descending portion of the duodenum, from 7 cm. to 10 cm. beyond the pylorus. The pancreatic duct, near the duodenum, is about the size of an ordinary quill. Sometimes the pancreatic duct and the common bile-duct open separately into the duodenum. Frequently there is an additional duct, which communicates with the pancreatic duct in the neck of the pancreas and opens into the duodenum about 2 cm. above the duodenal papilla. It receives the ducts from the lower part of the head, and is known as the *accessory pancreatic duct* (*ductus Santorini*).

Structure (fig. 1045).—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture.

FIG. 1045.—A section of the pancreas of a dog. $\times 250$.

It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects together the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, ending in a number of alveoli, which are tubular and somewhat convoluted. The minute ducts (intercalary ducts) connected with the alveoli are narrow and lined with flattened cells. In some animals spindle-shaped cells occupy the centre of the alveolus and are known as *centro-acinar cells*. These are prolongations of the terminal ducts. The true secreting cells which line the wall of the alveolus are columnar in shape and present two zones: an outer one, clear and faintly striated, next the basement membrane, and an inner one which contains secretory granules. In

hardened specimens the outer zone stains deeply with basic dyes, whereas the inner zone stains slightly. During activity the granular zone gradually diminishes in size; during the resting stages it gradually increases until it forms nearly three-fourths of the cell. In some of the secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cell; this is termed the *paranucleus*, and is believed to be derived from the nucleus. Between the alveoli are found, in certain parts, collections of cells, which are termed *interalveolar cell-islets*, or *islands of Langerhans*. The cells of these stain lightly with hematoxylin or carmine, and are more or less polyhedral in shape, forming a network in which many capillaries ramify. There are two main types of cell in the islets, distinguished as A-cells and B-cells according to the special staining reactions of the granules they contain. The cell-islets have been supposed to produce the internal secretion of the pancreas which is necessary for carbohydrate metabolism, but numerous researches have so far failed to elucidate their real function.

The wall of the pancreatic duct is thin, consisting of two coats, an external fibrous and an internal mucous; the latter is smooth, lined by columnar epithelium, and furnished near its termination with a few scattered follicles.

Vessels and Nerves.—The arteries of the pancreas are derived from the lienal artery, and from the pancreaticoduodenal branches of the hepatic and superior mesenteric arteries. Its veins open into the lienal and superior mesenteric veins. Its lymphatic vessels are described on p. 732. Its nerves are filaments from the lienal plexus.

Applied Anatomy.—Inflammation of the pancreas has of late years received considerable attention. It appears to be due to infection of the pancreatic ducts by micro-organisms from the duodenum in cases of gastroduodenal catarrh, or from the biliary passages in which a gall-stone is lodged. Acute cases usually terminate fatally and are frequently of the hemorrhagic type; chronic inflammation of the pancreas produces few symptoms of disease unless it is extensive, when attacks of abdominal pain, loss of appetite, progressive weakness and wasting, and the passage of whitish fatty motions, are likely to follow. Extensive fibrosis of the pancreas is also one of the commonest lesions found post-mortem in cases of diabetes mellitus. Cysts of the pancreas are sometimes met with. They may be the result of traumatism, when they generally contain blood, or they may be due to retention from obstruction of a duct, or from pressure on the main duct by a gall-stone. They may attain a large size, and cause symptoms by pressing on the stomach, Diaphragm, or common bile-duct. They generally push their way for-

wards between the stomach and transverse colon, and may then be felt as a definite tumour in the middle line of the upper part of the abdomen. The tumour is fixed and does not move with respiration. The treatment consists in opening the abdomen in the middle line, incising the cyst, evacuating its contents, and fixing its walls to the deeper layers of the abdominal wall. Drainage in the left loin, just below the last rib, can sometimes be established. When they are situated in the tail of the pancreas they have been removed. The pancreas is often the seat of cancer; this usually affects the head, and therefore speedily involves the common bile-duct, leading to persistent jaundice; or it may press upon the portal vein, causing ascites, or involve the stomach, causing pyloric obstruction. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found in company with other viscera, in rare cases of diaphragmatic hernia.

THE LIVER (HEPĀR).

The liver, the largest gland in the body, is situated in the upper and right parts of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and not uncommonly

FIG. 1046.—The superior, anterior, and right lateral surfaces of the liver.
(From a model by His.)

extending into the left hypochondrium as far as the mammary line. In the male it weighs from 1.4 to 1.6 kilogram., in the female from 1.2 to 1.4 kilogram. It is relatively much larger in the foetus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one-thirty-sixth of the entire body weight. Its greatest transverse measurement is from 20 cm. to 22 cm. Vertically, near its lateral or right surface, it measures from 15 cm. to 17 cm., while its greatest anteroposterior diameter is on a level with the upper end of the right kidney, and is from 10 cm. to 12 cm.; opposite the vertebral column its measurement from before backwards is reduced to about 7 cm. Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its colour is a dark reddish-brown, and its specific gravity is 1.05.

When the liver has been hardened *in situ* it presents the appearance of a wedge, the base of which is directed to the right and the edge to the left. Symington describes its shape as that of a right-angled triangular prism with the right angles rounded off.

The liver possesses five surfaces, viz. superior, inferior, anterior, posterior, and right. The inferior is separated from the superior, anterior, and right surfaces by a sharp margin, but the superior, anterior, and right surfaces are united by round borders. A sickle-shaped fold of peritoneum, named the falciform ligament, is attached by its convex edge to the Diaphragm and the anterior abdominal wall, and by its concave edge to the anterior and superior surfaces of the liver which it divides into a large right and a small left lobe (fig. 1046). In the free edge of this ligament there is a round cord, the *ligamentum teres hepatis*, which consists of the obliterated left umbilical vein.

Fossæ.—The inferior and posterior surfaces of the liver (figs. 1047, 1048) are traversed by five fossæ or fissures, arranged somewhat like the letter H. The left limb of the H is formed by the *left sagittal fossa*, which here separates the right and left lobes; it consists of an anterior part, the fossa for the umbilical vein, and a posterior part, the fossa for the ductus venosus. The right limb

FIG. 1047.—The posterior and inferior surfaces of the liver.
(From a model by Ilis.)

of the H is formed by the *right sagittal fossa*, the anterior of which is the fossa for the gall-bladder, the posterior, the fossa for the inferior vena cava. The cross-bar of the H is represented by the porta hepatis.

The *fossa for the umbilical vein* (fig. 1047) is a deep cleft which runs backwards from a notch (*incisura umbilicalis*) on the anterior margin of the liver to the left end of the porta hepatis, where it joins the fossa for the ductus venosus. It forms the left boundary of a four-sided area named the quadrate lobe, and a part of it is often bridged by a band of liver-substance, named the *pons hepatis*. In the foetus it lodges the left umbilical vein, and in the adult, the obliterated remains of this vein, viz. the *ligamentum teres hepatis*.

The *fossa for the ductus venosus* (fig. 1047) is a deep cleft on the posterior surface of the liver, separating the left lobe from an oblong area, named the caudate lobe. In the foetus it lodges the ductus venosus, and in the adult, a part of the lesser omentum, and a slender cord, named the *ligamentum venosum*, which represents the obliterated remains of the duct. The *ligamentum venosum* runs upwards and towards the right, in front of the upper end of the caudate lobe, and is attached to the wall of the inferior vena cava.

The *fossa for the gall-bladder* (fig. 1048) is a shallow depression on the inferior surface of the right lobe, parallel with, but on the right of, the fossa for the umbilical vein. It extends from the anterior margin of the liver, which is often notched by it, to the right extremity of the porta hepatis, and forms the right limit of the quadrate lobe.

The *fossa for the inferior vena cava* (fig. 1047) is a deep depression, occasionally a complete tunnel, on the posterior surface of the liver, between the caudate lobe and what is known as the 'bare area' of the right lobe (p. 1136). It is separated from the porta hepatis by a narrow band of liver-substance, named the *caudate process*. If the inferior vena cava be slit open the orifices of the hepatic veins will be displayed.

The *porta hepatis* (transverse fissure) (fig. 1048) is a deep fissure about 5 cm. long. It runs transversely between the posterior ends of the fossæ for the gall-bladder and umbilical vein, and separates the quadrate from the caudate lobe. Through the porta hepatis the portal vein, the hepatic artery and a plexus of nerves enter, and the right and left hepatic ducts and some lymphatic vessels leave, the liver. Near the right end of the porta hepatis the right and left hepatic ducts unite, at an obtuse angle, to form the hepatic duct. The hepatic duct and artery are placed in front of the portal vein, the duct lying

FIG. 1048.—The inferior surface of the liver. (From a model by His.)

on the right side of the artery. The lesser omentum is attached to the margins of the porta hepatis.

Lobes.—As already stated, the falciform ligament and the left sagittal fossa serve to divide the liver into a right and a left lobe.

The *left lobe* is thin, flattened from above downwards, and only about one-sixth of the size of the right. It presents superior, inferior and posterior surfaces which are described with the surfaces of the liver.

The *right lobe* is of a somewhat quadrilateral form. The porta hepatis and the fossæ for the gall-bladder and inferior vena cava traverse its posterior and inferior surfaces and divide its left portion into two smaller lobes, named the quadrate and caudate.

The *quadrate lobe* (figs. 1047, 1048) is situated on the inferior surface of the liver. It is bounded in front by the anterior margin, behind by the porta hepatis, on the right by the fossa for the gall-bladder, and on the left by the fossa for the umbilical vein. It is oblong in shape, its anteroposterior diameter being greater than its transverse.

The *caudate lobe* (Spigelian lobe) (fig. 1047) is situated on the posterior surface of the liver, opposite the lower three thoracic vertebræ. It is bounded above by the upper part of the ligamentum venosum, below by the porta hepatis, on the right by the fossa for the inferior vena cava, and on the left by the fossa for the ductus venosus. It has two free surfaces; one, quadrilateral in

shape, directed backwards and a little to the left, is separated from the Diaphragm by the superior recess of the omental bursa (p. 1092), the other, directed forwards and to the left, forms the right wall of the fossa for the ductus venosus, and is in contact with the part of the lesser omentum which lies in this fossa. A notch divides the projecting lower end of the lobe into a rounded left part, named the *papillary process*, and a narrow right part, termed the *caudate process*. The latter separates the porta hepatis from the fossa for the inferior vena cava, and connects the caudate lobe with the inferior surface of the main part of the right lobe (fig. 1048).

Surfaces.—The *superior surface* of the liver (fig. 1046) includes portions of the right and left lobes. It fits under the vault of the Diaphragm, and is covered by peritoneum, with the exception of a small triangular area between the diverging layers of the falciform ligament. Its right and left portions are convex, but on its central part there is a shallow *cardiac impression* which corresponds with the position of the heart on the upper surface of the Diaphragm.

The *anterior surface*, triangular in shape, also comprises portions of the right and left lobes, and is covered by peritoneum except at the line of attachment of the falciform ligament. A large part of this surface is in contact with the Diaphragm, which separates it on the right side from the sixth to the tenth ribs and their cartilages, and on the left side from the seventh and eighth costal cartilages. Its central part lies behind the xiphoid process of the sternum and, in the angle between the diverging right and left costal cartilages, the anterior abdominal wall.

The *right surface* is convex from before backwards, and slightly so from above downwards. It is covered by peritoneum and lies against the right portion of the Diaphragm which separates it from the lower parts of the right lung and pleura; outside these are the right costal arches from the seventh to the eleventh inclusive.

The *posterior surface* (fig. 1047) includes portions of the right and left lobes, and is thick and convex on the right, but thin on the left. Its central part is deeply concave in adaptation to the convexity formed by the vertebral column and the crura of the Diaphragm. A large part of this surface of the right lobe is not covered by peritoneum but is attached to the Diaphragm by areolar tissue. This non-peritoneal surface, or 'bare area' as it is termed, is triangular in shape, and is limited above and below by the superior and inferior layers of the coronary ligament. Its base is formed by the fossa for the inferior vena cava, while its apex, directed downwards and lateralwards, corresponds with the meeting-point of the two layers of the coronary ligament. Immediately to the right of the lower part of the fossa for the inferior vena cava is a small triangular pit, the greater part of which is on the bare surface; it lodges the right suprarenal gland and is named the *suprarenal impression*. Between the fossæ for the inferior vena cava and the ductus venosus is the caudate lobe, already described. Immediately to the left of the fossa for the ductus venosus, on the posterior surface of the left lobe, is the *œsophageal impression* in which the antrum cardiacum of the œsophagus is lodged.

The *inferior or visceral surface* (fig. 1048) is concave but uneven. It is directed downwards, backwards and towards the left, and is in contact with the stomach, duodenum, lesser omentum, right colic flexure, right kidney and right suprarenal gland. It is invested by peritoneum, except at the fossa for the gall-bladder and at the porta hepatis. On the inferior surface of the left lobe, and in direct continuity with the œsophageal groove, is the *gastric impression* which is moulded over the stomach. On the right of this impression is a rounded eminence, the *tuber omentale*; this fits into the concavity of the lesser curvature of the stomach, and is in contact with the lesser omentum. On the right of the fossa for the umbilical vein is the quadrate lobe which is concave and lies over the pyloric part of the stomach and the beginning of the duodenum, when these are dilated. When, on the other hand, the stomach is empty the quadrate lobe is in contact with the superior part of the duodenum and a portion of the transverse colon. Behind the quadrate lobe are the porta hepatis and the papillary and caudate processes, already described. There are three impressions, colic, renal and duodenal, on the part of the right lobe which is placed on the right side of the fossa for the gall-bladder. The *colic impression*, produced by the right colic flexure, is shallow and is situated anteriorly. The *renal impression*,

posterior to and deeper than the colic impression, is occupied by the upper part of the right kidney, and frequently extends for a short distance on to the lower part of the 'bare area.' The *duodenal impression* is between the renal impression and the neck of the gall-bladder. It is a narrow concave surface which comes into contact with the descending part of the duodenum.

The *anterior margin* of the liver is sharp, and marked, opposite the attachment of the falciform ligament by the incisura umbilicalis, and frequently by a second notch opposite the fundus of the gall-bladder. In adult males this margin generally corresponds with the lower edge of the thorax in the right mammary line, but in women and children it usually projects below the ribs.

Ligaments.—The liver is connected to neighbouring structures by ligaments. These, except the ligamentum teres hepatis and the ligamentum venosum, consist of folds or reflections of the peritoneum and comprise the falciform, coronary, right and left triangular, hepatogastric and hepatoduodenal ligaments.

The *falciform ligament* connects the liver to the Diaphragm and to the anterior abdominal wall and is a sickle-shaped fold consisting of two layers of peritoneum closely united together. Its convex margin is fixed to the inferior surface of the Diaphragm, and to the anterior abdominal wall as low as the umbilicus. Its concave margin is attached to the anterior and superior surfaces of the liver and to the fossa for the umbilical vein on its inferior surface. In its base or free edge are contained the ligamentum teres hepatis and the small paraumbilical veins. At the posterior part of the superior surface of the liver the two peritoneal layers of the falciform ligament separate from one another and expose a small triangular area which is uncovered by peritoneum. The right layer of the ligament is continuous with the superior layer of the coronary ligament, the left with the anterior layer of the left triangular ligament (fig. 1046).

The *coronary ligament* (fig. 1047) is formed by the reflections of the peritoneum from the liver to the Diaphragm at the upper and lower boundaries of the 'bare area,' and consists of a superior layer which is continuous with the right layer of the falciform ligament, and an inferior layer which passes on to the right kidney and suprarenal gland and is termed the *hepatorenal ligament*.

The *right triangular ligament* (right lateral ligament) (fig. 1046) is situated at the right extremity of the 'bare area,' and is a small fold which passes to the Diaphragm. It is formed by the apposition of the two layers of the coronary ligament.

The *left triangular ligament* (left lateral ligament) (fig. 1046) is larger than the right. It connects the posterior part of the upper surface of the liver to the Diaphragm, and its anterior layer is continuous with the left layer of the falciform ligament.

The *hepatogastric* and *hepatoduodenal* ligaments together constitute the lesser omentum which is attached below to the lesser curvature of the stomach and the superior part of the duodenum, and above to the liver along the margins of the porta hepatis and at the bottom of the fossa for the ductus venosus. Between the layers of the hepatoduodenal ligament are contained the common bile-duct, the portal vein and the hepatic artery, together with some lymph-glands and lymphatic vessels, and a plexus of nerves.

The *ligamentum teres hepatis* (fig. 1048) is a fibrous cord resulting from the obliteration of the left umbilical vein of the foetus. It runs from the umbilicus upwards and backwards in the free margin of the falciform ligament to the incisura umbilicalis, and above this in the fossa for the umbilical vein to the porta hepatis where it joins the left branch of the portal vein. Before birth the left umbilical vein conveyed blood from the placenta to the foetus.

The *ligamentum venosum* (*Arantii*) is a fibrous cord resulting from the obliteration of the ductus venosus. It ascends in the fossa for the ductus venosus and unites the left branch of the portal vein to the terminal part of the inferior vena cava. Before birth the ductus venosus transmitted to the inferior vena cava some of the blood conveyed from the placenta by the left umbilical vein.

Vessels and Nerves.—The vessels connected with the liver are the portal vein, and the hepatic artery and veins.

The *portal vein* and *hepatic artery*, accompanied by numerous nerves, ascend between the layers of the lesser omentum to the porta hepatis where each divides into two branches; the *bile-duct* and *lymphatic vessels* descend from the porta hepatis between

the layers of the same omentum. They are all enveloped in a loose areolar tissue, the *fibrous capsule of Glisson*, which accompanies the vessels in their course through the portal canals in the interior of the liver (fig. 1050).

The *hepatic veins* (fig. 1049) convey the blood from the liver to the inferior vena cava, and are described on p. 708. They have very little cellular investment, but what there is

FIG. 1049.—A longitudinal section of a hepatic vein. (After Kiernan.)

FIG. 1050.—A longitudinal section of a small portal vein and canal. (After Kiernan.)

binds them closely to the walls of the canals through which they run: so that, on section of the liver, they remain widely open and are solitary, and may be easily distinguished from the branches of the portal vein, which are more or less collapsed, and always accompanied by an artery and duct.

The *lymphatic vessels* of the liver are described on p. 731.

FIG. 1051.—A section of the injected liver (dog).

The *nerves* of the liver, derived from the *left vagus* and *sympathetic*, enter at the porta hepatis and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the medullated fibres are distributed almost exclusively to the coats of the blood-vessels; while the non-medullated enter the lobules and ramify between the cells.

Structure of the Liver.—The liver is dark reddish-brown in colour and is covered by peritoneum, underneath which is a thin capsule of connective tissue. With the naked eye the liver can be seen to consist of an enormous number of polyhedral lobules (fig.

1052), each of which is about 1 mm. in diameter. In the pig each lobule is sharply marked off from those adjoining it by connective tissue septa, but in the human liver there are no such definite boundaries.

A *lobule* consists of a mass of cells, arranged in columns which radiate from a central vein (fig. 1052). Between the columns are irregular blood-vessels (*sinusoids*).

A *liver-cell* is approximately cubical in shape, and is from 12μ to 25μ in diameter. It possesses one or two spherical *nuclei*, and its protoplasm usually contains granules of *glycogen*, and of a compound of *iron*. Fat droplets may also be present in the liver-cell.

Blood is conveyed to the liver by the portal vein and hepatic artery. These vessels enter the liver at the porta hepatis, and, as already stated, are enclosed together with the hepatic duct in a connective tissue sheath termed Glisson's capsule. In the porta hepatis the portal vein, hepatic artery and duct each divide into right and left branches, and these branches subsequently ramify, in their connective tissue capsule, throughout the substance of the liver, and are accompanied by nerves and lymphatic vessels. The spaces occupied by these various structures are named *portal canals* (fig. 1053). The smallest branches of the portal vein form *interlobular plexuses* between the liver lobules, and from these plexuses capillary-like vessels, named *sinusoids*, run between the columns of liver-cells and open into the *intralobular veins* in the centres of the lobules. The intra-lobular veins join to form *sublobular veins*, and these unite to form the *hepatic veins* (fig. 1049) which drain the blood from the liver into the inferior vena cava.

FIG. 1053.—A section across a portal canal of a pig. $\times 250$.

according to Herring and Simpson, minute channels penetrate the liver-cells, conveying the constituents of the blood into their substance.

The *bile-ducts* do not penetrate the lobules, but receive minute canaliculi which convey the bile from the cells to the periphery of the lobules. These canaliculi, or *bile-capillaries*, are merely little channels or spaces between adjacent cells, and are always separated from the sinusoids by at least half the width of a liver-cell (fig. 1054).

FIG. 1052.—A section across a lobule of a pig's liver. $\times 60$.

Structure of the ducts.—The walls of the biliary ducts consist of a connective tissue coat, in which are non-striped muscle-cells arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells resting on a basement membrane.

FIG. 1054.—The bile-capillaries of a rabbit, shown by Golgi's method. $\times 450$.

Nerve-fibrils are said to be distributed between the cells of the liver lobules, and even to enter their substance.

EXCRETORY APPARATUS OF THE LIVER

The excretory apparatus of the liver consists of (1) the *hepatic duct*, formed by the junction of the two main ducts, which leave the liver at the porta hepatis; (2) the *gall-bladder*, which serves as a reservoir for the bile; (3) the *cystic duct*, or duct of the gall-bladder; and (4) the *common bile-duct*, formed by the junction of the hepatic and cystic ducts.

The hepatic duct.—Two main ducts (right and left hepatic) issue from the liver at the porta hepatis and unite to form the hepatic duct, which passes downwards for about 3 cm., and is joined at an acute angle by the cystic duct; by the union of the two ducts the common bile-duct is formed. The hepatic duct is on the right of the hepatic artery and in front of the portal vein.

The gall-bladder (*vesica fellea*) (fig. 1055) is a conical or pear-shaped sac, lodged in a fossa on the under surface of the right lobe, and extending from near the right extremity of the porta hepatis to the anterior border of the liver. It is from 7 cm. to 10 cm. in length, 3 cm. in breadth at its widest part, and holds from 30 c.cm. to 50 c.cm. It is divided into a fundus, body, and neck. The *fundus*, or expanded end, is directed downwards, forwards, and to the right, and projects beyond the anterior border of the liver; the *body* is directed upwards, backwards, and to the left. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels; the under surface and sides are covered by peritoneum, which is continued from the surface of the liver. Occasionally the gall-bladder is completely invested by peritoneum, and may be connected to the liver by a short mesentery.

Relations.—The *body* of the gall-bladder is in relation, by its upper surface, with the liver; by its under surface, with the commencement of the transverse colon; and farther back usually with the upper end of the descending portion of the duodenum, but sometimes with the superior portion of the duodenum or pyloric end of the stomach. The *fundus*

is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind with the transverse colon. The *neck* is narrow; it curves upwards and forwards, and then, turning abruptly backwards and downwards, becomes continuous with the cystic duct; at its point of continuity with the cystic duct it presents

FIG. 1055.—The gall-bladder and bile-ducts laid open. (Spalteholz.)

a constriction. The neck is attached to the liver by areolar tissue in which the cystic artery is imbedded. Below the neck is the superior part of the duodenum.

Structure (fig. 1056).—The gall-bladder has three coats: serous, fibromuscular, and mucous.

The *external or serous coat* is derived from the peritoneum; it completely invests the fundus, but covers only the under surfaces and sides of the body and neck.

The *fibromuscular coat*, a thin but strong layer, consists of dense fibrous tissue, mixed with plain muscular fibres, which are disposed chiefly in a longitudinal direction, a few running transversely.

The *internal or mucous coat* is loosely connected with the fibrous layer. It is generally of a yellowish-brown colour, and is elevated into minute rugæ. Opposite the neck of the gall-bladder the mucous membrane projects inwards in the form of oblique ridges or folds, forming a sort of spiral valve. The mucous membrane is continuous through the hepatic duct with that of the ducts of the liver, and through the common bile-duct with that of the duodenum. Its epithelium is columnar, and secretes mucin, or, in some animals, a nucleoprotein.

Fig. 1056.—A transverse section of the wall of the gall-bladder.

The **cystic duct**, from 3 cm. to 4 cm. long, passes backwards, downwards, and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile-duct. The cystic duct runs parallel with and adheres to the hepatic duct for a short distance before joining with it. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a crescentic spiral valve. When the duct is distended, the spaces between the folds are dilated, and the exterior of the duct appears twisted.

The **common bile-duct** (*ductus choledochus*) is formed by the junction of the cystic and hepatic ducts; it is about 7 cm. long, and of the diameter of a goose-quill.

It runs at first downwards, backwards, and to the left in the right border of the lesser omentum, in front of the portal vein, and on the right of the hepatic artery. It passes behind the superior portion of the duodenum, and then runs in a groove, on the posterior surface of the head of the pancreas; here it is situated in front of the inferior vena cava, and is sometimes completely imbedded in the pancreatic substance. Its terminal part lies for a short distance along the right side of the terminal part of the pancreatic duct and passes with it obliquely through coats of the duodenum. The two ducts unite and open by a common orifice upon the summit of a papilla, situated at the medial side of the descending portion of the duodenum, 7 cm. to 10 cm. from the pylorus (fig. 1044). The short tube formed by the union of the two ducts is dilated into an ampulla, the ampulla of Vater.

Structure.—The coats of the large biliary ducts are an external or fibrous, and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissue, with a certain amount of muscular tissue, arranged, for the most part, in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts.

Applied Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the other abdominal viscera. The rupture may vary from a slight scratch to an extensive and complete laceration of its substance, dividing it into two parts. Sometimes an internal rupture, without laceration of the peritoneal covering, takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hæmorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. It may be injured by stabs or other punctured wounds, and when these are inflicted through the chest-wall, the pleural and peritoneal cavities may both be opened up, and both lung and liver wounded. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the epiploic foramen and placing the thumb on the lesser omentum, and compressing the hepatic artery and portal vein between the two. The margins of the laceration, if small, can be brought together and sutured by means of a blunt curved needle passed from one side of the wound to the other; this must be done with the greatest gentleness, as the liver substance is very friable. When the laceration is extensive it must be packed with gauze, the end of which is allowed to hang out of the external wound.

Abscess of the liver is of not infrequent occurrence. The so-called *tropical abscess* is due to absorption, from the intestine, of the amœba of dysentery, which reaches the liver through the portal system and causes the formation of a large chronic abscess; this may enlarge in many different directions on account of the relations of the liver to other organs. Thus it has been known to burst into the lungs, when the pus is coughed up; or into the stomach, when the pus is vomited; it may burst into the colon, or duodenum; or, by perforating the Diaphragm, it may empty itself into the pleural cavity. It often makes its way forwards, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardial cavities. Abscesses of the liver frequently require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and, unless the peritoneum is adherent, gauze is packed all round the exposed liver surface, the abscess opened, and a large drainage tube inserted.

Hydatid cysts are more often found in the liver than in any of the other viscera. The reason of this is not far to seek. The embryo of the egg of the *Tænia echinococcus*, being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a blood-vessel, and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid.

Ptosis of the liver, or hepatoptosis, from abnormal laxity of its ligaments and failure of the support it usually receives from the subjacent viscera, is an occasional cause of various nervous and gastro-intestinal disturbances. It has been very fully described by Glénard and his pupils. In women who have used very tight corsets and in men who have worn tightly buckled belts, the lower margin of the right lobe may become elongated by the pressure, producing an abnormal lobe known as the *linguiform* or *Riedel's lobe*. This may cause indefinite abdominal symptoms suggesting dyspepsia or disease of the gall-bladder; and if discovered accidentally, a Riedel's lobe may be mistaken for a tumour of the right kidney, of the colon or pancreas, or even of the vermiform process.

The gall-bladder may become distended in cases of obstruction of its duct or of the common bile-duct, or from a collection of gall-stones in its interior, thus forming a large tumour. The swelling is pear-shaped, and projects downwards and forwards towards the umbilicus. It moves with respiration, since it is attached to the liver. To relieve this condition, the gall-bladder must be opened (*cholecystotomy*) and the gall-stones removed. The operation is performed by an incision, 5 cm. to 7 cm. long, through the lateral part of the right Rectus, commencing at the costal margin. The peritoneal cavity is opened, and the tumour having been found, gauze is packed round it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised; any gall-stones in the bladder are now removed. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct. If this does

not succeed, the safest plan is to incise the duct, extract the stone, and close the incision by fine sutures in two layers. The obstruction having been removed, the edges of the incision in the gall-bladder may be sutured round a drainage tube which is inserted into the cavity; this fistulous opening usually closes in the course of a few weeks. The gall-bladder may be completely removed if it be quite certain that no cause for biliary obstruction remain: this is also done for primary malignant growth of the viscus.

Obstruction of the common bile-duct apart from stone is often due to occlusion of this canal by pressure of malignant growths, especially those commencing in the pylorus or pancreas. It is also seen following ulceration of the duct, cicatricial contraction of the scar tissue taking place. Enormous distension, both of the common duct itself and of its radicles in the liver substance, may occur at times.

UROGENITAL APPARATUS

The urogenital apparatus consists of (a) the urinary organs for the secretion, and discharge of the urine, and (b) the genital organs, which are concerned with the process of reproduction.

THE URINARY ORGANS

The urinary organs comprise the *kidneys*, which secrete the urine; the *ureters*, which convey it to the *urinary bladder*; and the *urethra*, through which it is discharged from the bladder.

THE KIDNEYS (RENES)

The *kidneys* are situated in the posterior part of the abdomen, one on either side of the vertebral column, behind the peritoneum, and are surrounded by a mass of fat and loose areolar tissue. Their upper extremities are on a level with the upper border of the twelfth thoracic vertebra, their lower, with the third lumbar vertebra. The right kidney is usually slightly lower than the left, probably on account of the vicinity of the liver; the left is a little longer and narrower than the right. The long axis of each kidney is directed downwards and lateralwards; the transverse axis lateralwards and backwards.

Each kidney is about 11 cm. in length, 6 cm. in breadth, and about 3 cm. in thickness. The weight of the kidney in the adult male varies from 125 gm. to 170 gm., in the adult female from 115 gm. to 155 gm.

The kidney has a characteristic form, and presents for examination two surfaces, two borders, and an upper and a lower extremity.

Relations.—The *anterior surface* (figs. 1042, 1057) of either kidney is convex, and looks forwards and lateralwards. Its relations to adjacent viscera differ on the two sides of the body.

(a) *Anterior surface of right kidney.*—A narrow portion at the upper extremity is in contact with the right suprarenal gland. A large area just below this and involving about three-fourths of the surface, lies in the renal impression on the inferior surface of the liver, and a narrow but somewhat variable area near the medial border is in contact with the descending part of the duodenum. The lower part of the anterior surface is in contact laterally with the right colic flexure, and medially, as a rule, with the small intestine. The area in relation with the small intestine and the greater part of the area in contact with the liver are covered by peritoneum; the suprarenal, duodenal, and colic areas are devoid of peritoneum.

(b) *Anterior surface of left kidney.*—A small area along the upper part of the medial border is in relation with the left suprarenal gland, and the upper two-thirds of the lateral half of the anterior surface are in contact with the renal impression on the spleen. A somewhat quadrilateral field, about the middle of the anterior surface, marks the site of contact with the body of the pancreas, on the deep surface of which are the lienal vessels. Above

this is a small triangular portion, between the suprarenal and splenic areas, in contact with the stomach. Below the pancreatic area the lateral part is

FIG. 1057.—The anterior surfaces of the kidneys, showing the areas of contact of the neighbouring viscera.

in relation with the left colic flexure, the medial with the small intestine. The areas in contact with the stomach and spleen are covered by the peritoneum of the omental bursa, while that in relation to the small intestine is covered by the peritoneum of the main cavity; behind the latter are some branches of

FIG. 1058.—The posterior surfaces of the kidneys, showing the areas of relation to the parietes.

the left colic vessels. The suprarenal, pancreatic, and colic areas are devoid of peritoneum.

The *posterior surface* (figs. 1058, 1059) of either kidney is directed backwards and medialwards. It is imbedded in areolar and fatty tissue, and is devoid of peritoneal covering. It lies upon the Diaphragm, the medial and lateral lumbocostal arches, the Psoas major, the Quadratus lumborum, and the tendon of origin of the Transversus abdominis, the subcostal, and one or two of the upper lumbar arteries, and the last thoracic, iliohypogastric, and ilio-inguinal nerves. The right kidney rests upon the twelfth rib, the left usually on the eleventh and twelfth. The Diaphragm separates the kidney from the pleura, which dips down to form the phrenicocostal sinus, but frequently the muscular fibres of the Diaphragm are defective or absent over a triangular area immediately above the lateral lumbocostal arch, and when this is the case the perinephric areolar tissue is in contact with the diaphragmatic pleura.

FIG. 1059.—The relations of the kidneys from behind.

The *superior extremity* is thick and rounded, and is nearer the median line than the lower; it is surmounted by the suprarenal gland, which covers also a small portion of the anterior surface.

The *inferior extremity*, smaller and thinner than the superior, extends to within 5 cm. of the iliac crest.

The *lateral border* is convex; that of the left kidney is in contact, at its upper part, with the spleen.

The *medial border* is concave in the centre, and convex towards either extremity; it is directed forwards and a little downwards. Its central part presents a deep vertical fissure, the *hilum*, which transmits the vessels, nerves and ureter, and is bounded by overhanging anterior and posterior lips. Above the hilum the medial border is in relation with the suprarenal gland.

The relative positions of the main structures in the hilum are as follows: the renal vein is in front, the artery in the middle, and the ureter behind and directed downwards. Frequently, however, branches of both artery and vein are placed behind the ureter.

The hilum expands into a central cavity termed the *renal sinus*: this contains the renal calyces and the upper part of the renal pelvis, surrounded by some fat in which the branches of the renal vessels and nerves are imbedded.

The *renal calyces*, from seven to thirteen in number, are cup-shaped tubes, each of which embraces one or more of the renal papillæ (p. 1147); they unite

to form two or three short tubes, and these in turn join to form a funnel-shaped sac, termed the *renal pelvis*.

FIG. 1060.—A sagittal section through the posterior abdominal wall showing the relations of the capsule of the kidney. (After Gerota.)

The renal pelvis, wide above and narrow below, is situated partly inside and partly outside the renal sinus, and is on a level with the spinous process of the first lumbar vertebra; at its neck or lower tapering end the ureter begins.

The kidney and its vessels are imbedded in a mass of fatty tissue, termed the *adipose capsule*, which is thickest at the borders of the kidney and is prolonged through the hilum into the renal sinus. The kidney and the adipose capsule are enclosed in a sheath of fibrous tissue continuous with the subperitoneal fascia, and named the *renal fascia* (figs. 1060, 1061). At the lateral border of the kidney the renal fascia splits into an anterior and a posterior layer. The anterior layer is carried medialwards in front of the kidney and its vessels,

and is continuous over the aorta with the corresponding layer of the opposite

side. The posterior layer extends medialwards behind the kidney and blends with the fascia on the *Quadratus lumborum* and *Psoas major*, and through this fascia is attached to the vertebral column. Above the suprarenal gland the two layers of the renal fascia fuse, and unite with the fascia of the Diaphragm; below they remain separate, and are gradually lost in the subperitoneal fascia of the iliac fossa. The renal fascia is connected to the fibrous tunic of the kidney by numerous trabeculae, which traverse the adipose capsule, and are strongest near the lower end of the organ. Behind the renal fascia is a

FIG. 1061.—A transverse section, showing the relations of the capsule of the kidney. (After Gerota.)

considerable quantity of fat, which constitutes the *paranephric body*. The kidney is held in position partly through the attachments of the renal fascia and partly by the apposition of the neighbouring viscera.

General structure of the kidney.—In the fetus the kidney consists of about twelve distinct lobules, but in the adult these are completely fused so that the organ presents a uniformly smooth surface. It is invested by a fibrous capsule which is easily stripped off; beneath the fibrous capsule is an incomplete layer of smooth muscle-fibres. The kidney is dense in texture, but is easily lacerable by mechanical force. If a vertical section be made from its convex to its concave border, and the loose tissue and fat removed from around the vessels and the excretory duct, the renal sinus will be seen surrounded at all parts but one by the proper kidney-substance (fig. 1062). The fibrous capsule is prolonged into the sinus round the lips of the hilum, to become continuous with the outer coat of the renal pelvis.

The kidney is composed of an internal *medullary* and an external *cortical* substance.

The *medullary substance* consists of a series of pale striated conical masses, termed the *renal pyramids*, the bases of which are directed towards the circumference of the kidney, while their apices converge towards the renal sinus, where they form prominent papillæ projecting into the interior of the calyces, each calyx receiving from one to three papillæ.

The *cortical substance* is reddish-brown in colour, and soft and granular in consistence. It lies immediately beneath the fibrous tunic, arches over the bases of the pyramids, and dips in between adjacent pyramids towards the renal sinus. The parts dipping in between the pyramids are named the *renal columns* (Bertini), while the portions which connect the renal columns with each other and intervene between the bases of the pyramids and the fibrous tunic are called the *cortical arches* (indicated between A and A' in fig. 1062). If the cortex be examined with a lens, it will be seen to consist of a series of lighter-coloured, conical areas, termed *medullary rays*, and a darker-coloured intervening substance, which from the complexity of its structure is named the convoluted part. The rays gradually taper towards the circumference of the kidney, and consist of a series of outward prolongations from the base of each renal pyramid.

The cortical and medullary substances are made up of renal tubules and blood-vessels, united and bound together by a connecting stroma.

Minute Anatomy.—The renal tubules (fig. 1063) commence in the cortical substance, and after pursuing a very tortuous course through the cortical and medullary substances finally end at the apices of the renal pyramids by open mouths. If the surface of one of the papillæ be examined with a lens, it will be seen to be studded over with minute openings, the orifices of the renal tubules, from sixteen to twenty in number, and if pressure be made on a fresh kidney, urine will be seen to exude from these orifices. The tubules commence in the convoluted part and renal columns as the *Malpighian bodies*, which are small rounded masses of a deep red colour, averaging about 0.2 mm. in diameter. Each of these bodies is composed of two parts: a central *glomerulus* of vessels, and a membranous envelope, the *capsule of Bowman*, which is the small pouch-like commencement of a renal tubule.

The *glomerulus* is a lobulated tuft of convoluted capillary blood-vessels, held together by scanty connective tissue. This capillary network is derived from a small arterial twig, the *afferent vessel*, which enters the capsule, generally at a point opposite to that at which the latter is connected with the tubule; the *efferent vessel* emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (figs. 1064, 1065).

Bowman's capsule is the blind expanded end of the renal tubule, indented for the reception of the glomerulus. It consists of a basement membrane, lined by a single layer of flattened epithelial cells. Thus between the glomerulus and the outer layer of the capsule there is a space lined by a continuous layer of squamous cells; this cavity varies in size according to the state of secretion and the amount of fluid present in it. In the fetus and young subject the lining epithelial cells are polyhedral or even columnar.

Each renal tubule consists of the following parts: (1) *Bowman's capsule*, already described, (2) a constricted portion, the *neck*, (3) the *first convoluted tubule*, (4) the *spiral*

FIG. 1062.—A vertical section of kidney.

tubule, which takes a course towards the medulla, (5) the descending limb of Henle's loop, narrower than the preceding, and running into the medullary substance, where it turns to form (6) the loop of Henle, (7) the ascending limb of Henle's loop, broader than the descending limb, which re-enters the cortical substance, (8) an irregular, angular

FIG. 1063.—A scheme of a renal tubule and its vascular supply.

FIG. 1064.—The distribution of the blood-vessels in the cortex of kidney.

FIG. 1065.—A glomerulus.

segment, the zig-zag tubule, (9) the second convoluted tubule, (10) the junctional tubule, which opens into (11) the collecting tubule (fig. 1063).

The straight or collecting tubules commence in the medullary rays of the cortex; they unite at short intervals with one another, the terminal tubes presenting a considerable increase in calibre, and are known as the ducts of Bellini; they finally open on the summit of one of the papillae.

Structure of the renal tubules.—The renal tubules consist of a basement membrane lined by epithelium. In the neck the epithelium is continuous with that lining Bowman's capsule, and like it consists of flattened cells each containing an oval nucleus (fig. 1067). The two convoluted tubules, the spiral and zigzag tubules, and the ascending limb of Henle's loop are lined by a type of epithelium which is histologically similar in all. The cells are somewhat columnar in shape and dovetail into one another on their lateral aspects. Each has a striated border next the lumen of the tube; its substance is granular, the granules in the outer portion being arranged in vertical rows. The nucleus is spherical and situated about the centre of the cell. In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat, clear epithelial plates, each with an oval nucleus (fig. 1066). The nuclei alternate on opposite surfaces of the tubule so that the lumen remains fairly constant.

In the straight tubule the epithelium is clear and cubical: in its papillary portion the cells are columnar and transparent (fig. 1068).

The renal blood-vessels.—Before entering the kidney, each artery divides into four or five branches which at the hilum lie mainly between the renal vein and ureter, the vein being in front, the ureter behind; one branch usually lies behind the ureter. Each vessel gives off some small branches to the suprarenal glands, to the ureter, and to the surrounding cellular tissue and muscles.

Frequently a second renal artery, termed the *inferior renal*, is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney, whilst occasionally an additional artery enters the upper part of the kidney. The branches of the renal artery, while in the sinus, give off a few twigs for the nutrition of the surrounding tissues, and end in the *arterie propriae renales*, which enter the kidney proper in the

FIG. 1066.—A longitudinal section of the descending limb of Henle's loop.

a. Membrana propria. b. Epithelium.

FIG. 1067.—A section of the cortex of a human kidney ×250.

renal columns. Two of these pass to each renal pyramid, and run along its sides for its entire length, giving off in their course the afferent vessels of the Malpighian bodies in the renal columns. Having arrived at the bases of the pyramids, they form arterial arches or arcades which lie in the boundary zone between the bases of the pyramids and the cortical arches, the convexity of the vessels being towards the surface of the kidney.

Interlobular arteries (fig. 1063) are given off from the convex side of the arterial arcade, and pass directly outwards between the medullary rays to reach the fibrous tunic, where they end in the capillary network of this part. These vessels do not anastomose with each other, but form what are called *end-arteries*. In their outward course they give off the *afferent vessels* for the glomeruli (p. 1147). From each glomerulus the corresponding *efferent vessel* arises, and breaks up into a number of branches which form a dense *plexus* around the adjacent renal tubules.

A *second set of branches* from the arterial arcades supply the renal pyramids, which they enter at their bases; and, passing straight through their substance to their apices, terminate in the *plexuses* found in that situation. They are called the *arteriæ rectæ*. The efferent vessels from the glomeruli nearest the medulla break up into leashes of straight vessels (*false arteriæ rectæ*) which pass down into the medulla and join the plexus of vessels there (fig. 1063).

The *renal veins* arise from three sources, viz. the veins beneath the fibrous tunic, the plexuses around the convoluted tubules in the cortex, and the plexuses situated at the apices of the renal pyramids. The veins beneath the fibrous tunic (*venæ stellatæ*) are stellate in arrangement, and are derived from the capillary network into which the terminal branches of the interlobular arteries break up. These form the commencement

Fig. 1068.- A transverse section of the pyramidal substance of the kidney of a pig, the blood-vessels of which were injected.

of the *interlobular veins*, which pass inwards between the rays, receive branches from the plexuses around the convoluted tubules, and, having arrived at the bases of the pyramids, join the convex sides of the venous arches.

The *venæ rectæ* arise from the plexuses at the apices of the medullary pyramids. They run outwards in a straight course between the tubes of the medullary substance, and join the concave sides of the venous arcades; these in turn unite and form veins which pass along the sides of the pyramids (fig. 1063).

The latter vessels, *venæ propriae renales*, accompany the arteries of the same name, and quit the kidney substance to enter the sinus. In this cavity they join the corresponding veins from the other pyramids to form the *renal vein*, which emerges from the kidney at the hilum and opens into the inferior vena cava; the left vein is longer than the right, and crosses in front of the abdominal aorta.

Nerves of the kidney.—The *nervus* of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the coeliac plexus, the lower and outer part of the coeliac ganglion and aortic plexus, and from the lesser and lowest splanchnic nerves. The *spinal nerves* which supply the kidney are derived from the tenth, eleventh, and twelfth thoracic segments of the medulla spinalis. The nerves communicate with the testicular plexus, a circumstance which may explain the occurrence of pain in the testis in affections of the kidney. They accompany the renal artery and its branches, and are distributed to the blood-vessels and to the cells of the urinary tubules.

The *lymphatics* of the kidney are described on p. 782.

Connective tissue, or intertubular stroma.—Although the tubules and vessels are closely packed, a small amount of connective tissue, continuous with the fibrous tunic, binds them firmly together and supports the blood-vessels, lymphatics, and nerves.

Applied Anatomy.—Malformations of the kidney are not uncommon. There may be an entire absence of one kidney, but, according to Morris, the number of these cases is

'excessively small': or there may be congenital atrophy of one kidney, when the kidney is very small, but usually healthy in structure. These cases are of great importance, and must be duly taken into account when nephrectomy is contemplated. A more common malformation is where the two kidneys are fused together. They may be joined together only at their lower ends by means of a thick mass of renal tissue, so as to form a horseshoe-shaped body, or they may be completely united, forming a disc-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well. In some mammals (e.g. ox and bear) the kidney consists of a number of distinct lobules; this lobulated condition is characteristic of the kidney of the human foetus, and traces of it may persist in the adult. Sometimes the pelvis is duplicated, while a double ureter is not very uncommon.

One or both kidneys may be misplaced as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher, though this is very uncommon, or lower than normal, or removed farther from the vertebral column than usual; or they may be displaced into the iliac fossa, over the sacro-iliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed; it is then known as a *floating kidney*. It is believed to be due to the fact that the kidney is completely enveloped by peritoneum, which passes backwards to the vertebral column as a double layer, forming a mesonephron which permits of movement taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues by which it is surrounded, moving in the perinephric tissues. This condition is known as *movable kidney*, and is more common in the female than in the male. It occurs in badly nourished people, or in those who have become emaciated from any cause. It must not be confounded with the *floating kidney*, which is a congenital condition due to the development of a mesonephron.

Injuries of the kidney are generally due to some severe crushing force, as from being run over by a heavy waggon or cart, or from the abdomen being compressed between the buffers of two railway carriages. When a laceration occurs on the posterior surface of the organ, infiltration of blood and urine takes place into the retroperitoneal connective tissue; this is often followed by suppuration, and death may ensue from septic poisoning. When the laceration is in front, the peritoneum may be torn and extravasation of blood and urine may take place into the peritoneal cavity. Death may occur from hæmorrhage or peritonitis. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydronephrosis follow. Sometimes the kidney may be bruised by blows in the loin, or by being compressed between the lower ribs and the ilium when the body is violently bent forwards. This is followed by a little transient hæmaturia, which, however, speedily passes off.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephric abscess*. This may be due to injury, or to disease of the kidney itself, or to extension of inflammation from neighbouring parts. The abscess tends to point externally in the groin or loin.

Tumours of the kidney may be recognised by their position: by the resonant colon lying in front of them; and by their rounded outline not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The *hypernephroma*, a tumour arising from suprarenal 'rests' or inclusions in the cortex or medulla of the kidney, is not infrequent. When occurring in children it is often associated with precocious growth of the body generally and of the hair and sexual organs in particular. Arising, as it often does, in the kidney, a hypernephroma is indistinguishable from a true renal tumour so far as the physical signs and symptoms go; it is really, however, a tumour of the suprarenal gland substance.

The examination of the kidney should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forwards, while the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation, sometimes with faintness.

The kidney may require exposure for exploration or the evacuation of pus (*nephrotomy*); it may be incised for the removal of stone (*nephrolithotomy*); it may be sutured when movable or floating (*nephropexy*); or it may be removed (*nephrectomy*). It may be exposed either by a lumbar or an abdominal incision; except in cases of very large tumours, a lumbar incision is best, as it has the advantages of not opening the peritoneum, and of affording admirable drainage. An oblique incision should be made, starting at the lateral border of the Sacrospinalis, 1 cm. below the last rib and directed downwards and forwards towards a point 2.5 cm. in front of the anterior superior spine of the ilium. The structures divided are the skin, the superficial fascia with the cutaneous nerves, the deep fascia, the posterior border of the Obliquus externus abdominis, and the outer border of the Latissimus dorsi; the Obliquus internus and the posterior aponeurosis of the Transversus abdominis; the lateral border of the Quadratus lumborum; the deep layer of the lumbodorsal fascia and the transversalis fascia. The fatty tissue around the kidney is now exposed to view, and must be separated by the fingers, or a director, in order to reach the kidney. The operations of nephrolithotomy, for the removal of calculi from the kidney, and nephrotomy, or incision of the kidney for abscess, &c., are generally

performed by the lumbar incision, especially if the organ contains pus. The abdominal operation is best performed by an incision in the lateral part of the Rectus abdominis on the side of the kidney to be removed.

This route is also generally chosen for nephrectomy. The abdominal operation is best performed by an incision in the lateral part of the Rectus abdominis on the side of the kidney to be removed. The incision is then reached from the lateral side of the colon, ascending or descending, as the case may be, and thus the vessels of the colon are not interfered with. The incision commencing just below the costal arch is made of varying length, according to the size of the kidney. The abdominal cavity having been opened, the intestines are drawn medialwards and the peritoneum covering the kidney to the lateral side of the colon is incised, so that the fingers can be introduced behind the peritoneum. The kidney must now be enucleated, and the vessels firmly ligatured and divided, the ureter being tied separately. The particular advantage of the abdominal operation is that the condition of the other kidney can be ascertained by manual examination, before the removal of the diseased kidney is finally decided upon; and, further, involvement of neighbouring structures by a new growth, rendering removal impossible, can only be discovered by the abdominal route.

Nephropexy is the name given to the operation for fixing a movable kidney. The kidney is reached by the lumbar incision, and is freely separated from its perinephric capsule. Sutures are then passed through the true capsule of the organ and are brought out above the upper end of the wound. When these sutures are tied, the kidney is tightly anchored in position; at the same time a flap of the true capsule can be separated from the parenchyma of the kidney and passed around the last rib and sutured down again, so as to form a sling for the kidney from the rib.

THE URETERS

The **ureters** are the two tubes which convey the urine from the kidneys to the urinary bladder. Each measures from 25 cm. to 30 cm. in length, and is a thick-walled, narrow, cylindrical tube which is directly continuous, near the lower end of the kidney, with the tapering extremity of the renal pelvis. It runs downwards and medialwards in front of the Psoas major and, entering the pelvic cavity, finally opens into the fundus of the urinary bladder.

The *abdominal part* lies behind the peritoneum on the medial part of the Psoas major, and is crossed obliquely by the testicular vessels. It enters the pelvic cavity by crossing either the termination of the common, or the commencement of the external, iliac vessels.

At its origin the *right* ureter is usually covered by the descending part of the duodenum; in its course downwards it lies to the right of the inferior vena cava, and is crossed by the right colic and ileocolic vessels, while near the superior aperture of the pelvis it passes behind the lower part of the mesentery and the terminal part of the ileum. The *left* ureter is crossed by the left colic vessels, and near the superior aperture of the pelvis passes behind the sigmoid colon and its mesentery.

The *pelvic part* runs at first downwards on the lateral wall of the pelvic cavity, along the anterior border of the greater sciatic notch and under cover of the peritoneum. It lies in front of the hypogastric artery, and medially to the obturator nerve and the umbilical, obturator, inferior vesical, and middle hæmorrhoidal arteries. Opposite the lower part of the greater sciatic foramen it inclines medialwards, and reaches the lateral angle of the urinary bladder, where it is situated in front of the upper end of the seminal vesicle (and at a distance of about 5 cm. from the opposite ureter); here the ductus deferens crosses to its medial side, and the vesical veins surround it. Finally, the ureters run obliquely for about 2 cm. through the wall of the bladder and open by slit-like apertures into the cavity of that viscus at the lateral angles of the trigone. When the bladder is distended the openings of the ureters may be about 5 cm. apart, but when it is empty and contracted the distance between them is diminished by one-half. Owing to their oblique course through the coats of the bladder, the upper and lower walls of the terminal portions of the ureters become closely applied to each other when the bladder is distended, and, acting as valves, prevent regurgitation of urine.

In the *female*, the ureter forms, as it lies in relation to the wall of the pelvis, the posterior boundary of a shallow depression named the *ovarian fossa*, in which the ovary is situated. It then runs medialwards and forwards on the lateral aspect of the cervix uteri and upper part of the vagina to reach the fundus of the bladder. In this part of its course it is accompanied for about 2.5 cm. by the uterine artery, which then crosses in front of the ureter.

and ascends between the two layers of the broad ligament. The ureter is distant about 2 cm. from the side of the cervix of the uterus.

The ureter is sometimes duplicated on one or both sides, and the two tubes may remain distinct as far as the fundus of the bladder; they rarely open separately into the bladder cavity.

Structure (fig. 1069).—The ureter is composed of three coats: fibrous, muscular, and mucous.

The *fibrous coat* is continuous at one end with the fibrous tunic of the kidney on the floor of the renal sinus; while at the other it is lost in the fibrous structure of the bladder.

In the renal pelvis the *muscular coat* consists of two layers, longitudinal and circular: the longitudinal fibres become lost upon the sides of the papillæ at the extremities of the calyces; the circular fibres surround the medullary substance in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers: an external longitudinal, a middle circular, and an internal, less distinct than the other two, but having a general longitudinal direction.

FIG. 1069.—A transverse section through the ureter of a sheep. Stained with hæmatoxylin and eosin. $\times 25$.

The *mucous coat* is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, while it is prolonged over the papillæ of the kidney above. It consists of fibrous tissue containing many elastic fibres, and covered by transitional epithelium. The continuation of the epithelium over the renal papillæ is columnar in type.

The *arteries* supplying the ureter are branches from the renal, testicular or ovarian, hypogastric, and inferior vesical arteries.

The *nerves* are derived from the inferior mesenteric, spermatic, and pelvic plexuses; through these plexuses fibres are derived from the lower three thoracic and first lumbar segments of the medulla spinalis. Small ganglia and isolated ganglion-cells are found in the fibrous and muscular coats.

Applied Anatomy.—Rupture of the ureter is not a common accident, but occasionally occurs. If it be torn completely across, the urine collects in the retroperitoneal tissues; if it be not completely divided, the lumen of the tube may become strictured, and hydro-nephrosis or pyonephrosis result. The ureter may be accidentally wounded in some pelvic operations, such as removal of the uterus; if this should happen the divided ends must be sutured together, or failing to accomplish this an attempt may be made to implant the upper end into the bladder or rectum. If this cannot be carried out the only alternative is to remove the kidney immediately.

Stones not uncommonly become impacted in the ureter. These may occur at any part, but most commonly either at the point where the tube is crossing the pelvic brim or at the termination, where it is passing obliquely through the muscular wall of the bladder. In the former case, an incision with its centre opposite, and 2.5 cm. medially to, the anterior superior iliac spine dividing all the structures down to the peritoneum, enables

the operator to reach the ureter by pushing the unopened peritoneum inwards; the stone can then be felt in the ureter, the wall of which is incised, and the stone extracted, free drainage being provided for the escaping urine. When the stone is impacted at the vesical end of the tube a preliminary incision into the bladder is required, and by scratching through the mucous membrane overlying it the calculus can be removed.

THE URINARY BLADDER (VESICA URINARIA)

The urinary bladder (fig. 1070) is a sac which acts as a reservoir for the urine; its size and position vary with the amount of fluid it contains, and also with the state of distension of the neighbouring viscera.

FIG. 1070.—A median sagittal section through the male pelvis.

When the empty bladder is firmly contracted it has the form of a flattened tetrahedron. It has a fundus, a vertex, a superior and an inferior surface. The *fundus* (fig. 1071) is triangular in shape, and is directed downwards and backwards towards the rectum, from which it is separated by the rectovesical fascia, the vesiculæ seminales, and the terminal portions of the ductus deferentes. The *vertex* is directed forwards towards the upper part of the symphysis pubis, and from it the middle umbilical ligament (urachus) is continued upwards on the back of the abdominal wall to the umbilicus; the peritoneum folded over this ligament forms the middle umbilical fold. The *superior surface* is triangular, covered by peritoneum, and is in relation with the sigmoid colon and some coils of the small intestine. It is bounded on either side by a lateral border which separates it from the inferior surface, and behind by a posterior border, represented by a line joining the two ureters, which intervenes between it and the fundus. The lateral borders run from the ureters to the vertex, and from these borders the peritoneum extends to the walls of the pelvis. On either side of the bladder is a peritoneal depression named the *parametral fossa* (fig. 1001). The *inferior surface* is directed downwards, and is uncovered

by peritoneum. It may be divided into a posterior or prostatic area and two inferolateral surfaces. The prostatic area, somewhat triangular, rests upon and

FIG. 1071.—The fundus of the urinary bladder, &c.

is in direct continuity with the base of the prostate; from it the urethra emerges. The inferolateral portions of the inferior surface are separated in front from the symphysis pubis by a mass of fatty tissue named the *retropubic pad*; behind,

FIG. 1072.—A sagittal section through the pelvis of a new-born male child.

they are in contact with the fascia covering the Levatores ani and Obturatores interni.

When the bladder is empty it is placed entirely within the pelvis, the level of the obliterated hypogastric arteries, and below the portions of the ductus deferentes which are in contact with the of the pelvis.

As the bladder fills, its fundus, being more or less fixed, is only slightly depressed; while its superior surface gradually rises into the abdominal cavity, carrying with it its peritoneal covering, and at the same time rounding off the posterior and lateral borders. When the bladder is distended it assumes an ovoid form, the long diameter being directed upwards and forwards. In this condition it presents a posterosuperior, an antero-inferior, and two lateral surfaces, a fundus, and a summit. The posterosuperior surface is directed upwards and backwards, and is covered by peritoneum; behind, it is separated from the rectum by the rectovesical excavation, while its anterior part is in contact with the coils of the small intestine. The antero-inferior surface is devoid of peritoneum, and rests, below, against the pubic bones, above which it is in contact with the back of the anterior abdominal wall. The lower

FIG. 1078.—A sagittal section through the pelvis of a new-born female child. Some coils of the small intestine separated the uterus from the bladder.

parts of the lateral surfaces are destitute of peritoneum, and are in contact with the lateral walls of the pelvis. The line of peritoneal reflection from the lateral surface is raised to the level of the obliterated hypogastric artery. The fundus undergoes little alteration in position, being only slightly lowered. It exhibits, however, a narrow triangular area, which is separated from the rectum merely by the rectovesical fascia. This area is bounded below by the prostate, above by the rectovesical fold of peritoneum, and laterally by the ductus deferentes. The ductus deferentes frequently come in contact with each other above the prostate, and under such circumstances the lower part of the triangular area is obliterated. The line of reflection of the peritoneum from the rectum to the bladder appears to undergo little or no change when the latter is distended; it is situated about 10 cm. from the anus. The summit of the bladder is directed upwards and forwards above the point of attachment of the middle umbilical ligament, and hence the peritoneum, which follows the ligament, forms a pouch of varying depth between the summit and the anterior abdominal wall.

In the new-born child (figs. 1072, 1073) the internal urethral orifice is at the level of the upper border of the symphysis pubis; the bladder therefore lies relatively at a much higher level in the infant than in the adult. Its anterior surface is in contact with about the lower two-thirds of that part of the abdominal wall which lies between the symphysis pubis and the umbilicus (Symington *). Its fundus is clothed with peritoneum as far as the level of the

internal orifice of the urethra. Although the bladder of the infant is usually described as an abdominal organ, Symington has pointed out that only about one-half of it lies above the plane of the superior aperture of the pelvis. Dine maintains that the internal urethral orifice sinks rapidly during the first three years, and then more slowly until the ninth year, after which it remains stationary until puberty, when it again slowly descends and reaches its adult position.

In the female, the bladder is in relation behind with the uterus and the upper part of the vagina (fig. 1074). It is separated from the anterior surface of the body of the uterus by the vesico-uterine excavation, but below the

FIG. 1074.—A median sagittal section through a female pelvis.

level of this excavation it is connected to the front of the cervix uteri and the upper part of the anterior wall of the vagina by areolar tissue. When the bladder is empty the uterus rests upon its superior surface.

Ligaments.—The bladder is connected to the pelvic wall by the fascia endopelvis. In front this fascial attachment is strengthened by a few muscular fibres, the *Pubicocystales*, which extend from the back of the pubic bones to the front of the bladder; behind other muscular fibres run from the fundus of the bladder to the sides of the rectum, in the sacrogenital folds, and constitute the *Rectovesicales*.

The vertex of the bladder is joined to the umbilicus by the remains of the umbilus which forms the *middle umbilical ligament*, a fibromuscular cord broad at its attachment to the bladder but narrowing as it ascends.

From the superior surface of the bladder the peritoneum is carried off in a series of folds which are sometimes termed the *false ligaments of the bladder*. Anteriorly there are three folds, the *middle umbilical fold* on the middle umbilical ligament, and two *lateral vesical folds* on the obliterated hypogastric arteries. The reflections of the peritoneum on to the side walls of the pelvis

form the lateral false ligaments, while the rectovesical or sacrogenital folds (p. 1089) constitute the posterior false ligaments.

Interior of the bladder (fig. 1075).—The mucous membrane lining the bladder is, over the greater part of the viscus, loosely attached to the muscular coat, and appears wrinkled or folded when the bladder is contracted; the folds are effaced when the bladder is distended. Over a small triangular area, termed the *trigonum vesicæ*, immediately above and behind the internal orifice of the urethra, the mucous membrane is firmly bound to the muscular coat, and is always smooth. The anterior angle of the trigonum vesicæ is formed by the internal orifice of the urethra; its posterolateral angles by the orifices of the ureters. Stretching between the latter openings is a slightly curved ridge, the *torus uretericus*, forming the base of the trigone and produced

FIG. 1075.—The interior of the bladder.

by an underlying bundle of non-striped muscular fibres. The lateral parts of this ridge extend beyond the openings of the ureters, and are named the *plicæ uretericæ*; they are produced by the terminal portions of the ureters as they traverse obliquely the bladder wall. When the bladder is illuminated the torus uretericus appears as a pale band and forms an important guide during the operation of introducing a catheter into the ureter.

The *orifices of the ureters* are placed at the posterolateral angles of the trigonum vesicæ, and are usually slit-like in form. In the contracted bladder they are about 2.5 cm. apart and about the same distance from the internal urethral orifice; in the distended viscus these measurements may be increased to about 5 cm.

The *internal urethral orifice* is placed at the apex of the trigonum vesicæ, in the most dependent part of the bladder, and is usually somewhat crescentic in form; the mucous membrane immediately behind it exhibits a slight elevation, the *uvula vesicæ*, caused by the middle lobe of the prostate.

Structure (fig. 1076).—The bladder is composed of four coats: serous, muscular, sub-mucous, and mucous.

This *serous coat* is a partial one, and is derived from the peritoneum. It invests the

superior surface and the upper parts of the lateral surfaces, and is reflected from these on to the abdominal and pelvic walls.

The *muscular coat* consists of three layers of unstriated muscular fibres: an external and an internal of longitudinal fibres, and a middle of circular fibres.

The *fibres of the external longitudinal layer* arise from the posterior surface of the body of the os pubis in both sexes (*musculi pubovesicales*), and in the male from the adjacent part of the prostate and its capsule. They pass, in a more or less longitudinal manner, up the inferior surface of the bladder, over its vertex, and then descend along its fundus to become attached to the prostate in the male, and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. This layer has been named the *Detrusor urinae* muscle.

The *fibres of the middle circular layer* are very thinly and irregularly scattered on the body of the organ, and, although to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Towards the lower part of the bladder, round the internal urethral orifice, they are disposed in a thick circular layer, forming the *Sphincter vesicae*, which is continuous with the muscular fibres of the prostate.

The *internal longitudinal layer* is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate, and are inserted by means of a fibrous process into the middle lobe of that organ. They are the *muscles of the ureters*, described by Sir C. Bell, who supposed that during the contraction of the bladder they serve to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The *submucous coat* consists of a layer of areolar tissue, connecting together the muscular and mucous coats, and intimately united with the latter.

The *mucous coat* is thin, smooth, and of a pale rose colour. It is continuous above with that of the ureters, and below with that of the urethra; the epithelium covering it is of the transitional variety. The loose texture of the submucous layer allows the mucous coat to be thrown into folds or *rugae* when the bladder is empty. Over the trigonum vesicae the mucous membrane is closely attached to the muscular coat, and is not thrown into folds, but is smooth and flat. There are no true glands in the mucous membrane of the bladder, though certain mucous follicles which exist, especially near the neck of the bladder, have been regarded as such.

Vessels and Nerves.—The principal *arteries* of supply to the bladder are the superior, middle, and inferior vesical, derived from the anterior trunk of the hypogastric artery. The obturator and inferior gluteal arteries also send small branches to it, and in the female additional branches are derived from the uterine and vaginal arteries.

The *veins* form a complicated plexus on the inferior surface and fundus near the prostate, and end in the hypogastric veins.

The *lymphatics* are described on p. 788.

The *nerves* of the bladder are (1) fine medullated fibres from the second, third, and fourth sacral nerves, and (2) non-medullated fibres from the hypogastric plexus. They are connected with ganglia in the outer and submucous coats, and are finally distributed, all as non-medullated fibres, to the muscular layer and epithelial lining of the viscus.

Applied Anatomy.—A defect of development, in which the bladder is implicated, is known under the name of *extroversion of the bladder*. In this condition the lower part of the abdominal wall as high as the umbilicus, and the anterior wall of the bladder are wanting, so that the posterior wall of the bladder presents on the abdominal surface, and is pushed forwards by the pressure of the viscera within the abdomen, forming a red vascular tumour on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra, a condition known as *epispadias*. The pelvic bones are also arrested in development (p. 808).

When the bladder is distended, it may be ruptured by violence applied to the abdominal wall, without any injury to the bony pelvis, or it may be torn in cases of

FIG. 1076.—A vertical section of the wall of the bladder.

fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal; that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lambert's suture are resorted to, with a very considerable amount of success. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder*. Between these muscular bundles the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder*, and in these little pouches phosphatic concretions may collect, forming *encysted calculi*.

Various forms of tumour have been found springing from the wall of the bladder. The commonest innocent tumour is the villous papilloma. Of the malignant tumours, epithelioma is the most common. In doubtful cases the cystoscope proves a valuable aid in diagnosis. This instrument consists of a tube in which is fixed a small electric light, the wires of which run through the shaft of the instrument. Upon introducing this down the urethra, the bladder can be examined with the eye, and a villous growth or other tumour, a calculus, or an ulcer can be detected; or the orifices of the ureters can be examined, and renal hæmaturia diagnosed, and it can be definitely settled from which kidney the blood comes. Again, the presence of a minute tuberculous ulceration near the mouth of the ureter on the affected side may establish the diagnosis, not only of tuberculous kidney, but also of the side in which the disease is located. The cystoscope can be used to catheterise the ureter, for the purpose of obtaining a specimen of urine from either kidney, or to ascertain the condition of both kidneys where it is proposed to remove one. Ureteric bougies opaque to x-rays can be passed up and photographed.

Puncture of the bladder may be performed either above the symphysis pubis or through the rectum, in both cases without wounding the peritoneum. The former plan is generally to be preferred, since in puncture by the rectum a permanent fistula may be left from an abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a canula in the rectum. In some cases in performing this operation the rectovesical excavation of the peritoneum has been wounded, inducing fatal peritonitis. Puncture through the rectum, therefore, has been almost completely abandoned in favour of the suprapubic route.

Access to the bladder, for the purpose of removing calculi or an enlarged prostate, is almost always effected by the suprapubic route, the old perineal operation being rarely resorted to. In the female, owing to the shortness of the urethra and its ready dilatability, calculi and foreign bodies and few growths, when of small size, may be removed by the urethral route.

Suprapubic cystotomy is performed by first injecting ten or twelve ounces of some weak antiseptic fluid into the bladder. Then, with or without distending the rectum, a vertical median incision, from 7 to 10 cm. in length, is made in the hypogastric region immediately above the symphysis, and extended between the *Pyramidales* and *Recti* until the *transversalis fascia* is reached. This is divided and some fatty tissue exposed (space of Retzius). Upon separating this, the anterior surface of the bladder will be exposed and will be recognised by its muscular fibres. A needle should be passed through its coat on either side of the spot selected for the opening, and two long pieces of silk inserted. The bladder is incised between these stays, which are held by an assistant and form a useful guide to the opening in the bladder when the fluid has escaped.

It is important that the bladder should be emptied by catheter as a routine measure in women, prior to operations on the lower part of the abdomen or pelvis. Neglect of this precaution has, not uncommonly, led to that viscus being opened by accident. Women especially are apt to acquire an chronic distension of the bladder, and the fact that some quantity of urine has been passed immediately before the operation is no guarantee that the viscus is not distended. If the accident should occur, the bladder wall must be carefully sutured before the peritoneum is opened.

THE MALE URETHRA (fig. 1072)

The male urethra, from 18 cm. to 20 cm. long, extends from the internal urethral orifice in the urinary bladder to the external urethral orifice at the end of the penis. It presents a double curve in the ordinary relaxed state of the penis (fig. 1072). Except during the passage of fluid along it, the urethral canal is a mere slit or cleft; in the prostatic portion the slit is transversely situated; in the membranous portion irregular or oblique; in the cavernous portion transverse; while at the external orifice it is vertical. It is divided into three portions, prostatic, membranous, and cavernous, which differ in structure and relations.

The prostatic portion, the widest and most dilatable part of the urethra, is about 2 cm. long, and runs almost vertically through the prostate from its base to a point on its anterior surface, a little above the apex. It lies nearer the anterior than the posterior surface of the prostate. It is wider in the middle than at either end, and narrowest below, where it joins the membranous portion; in transverse section it is horseshoe-shaped with the convexity directed forwards.

Upon the posterior wall or floor is a narrow longitudinal ridge, the *urethral crest* (*verumontanum*) formed by an elevation of the mucous membrane and its subjacent tissue. It is about 15 mm. long, and about 3 mm. high, and contains, according to Kobelt, muscular and erectile tissue. (When distended, it may serve to prevent the passage of the semen backwards into the bladder.) On either side of the crest is a slight depression, the *prostatic sinus*, the floor of which is perforated by the *orifices of the prostatic ducts* from the lateral lobes of the prostate; the ducts of the middle lobe open proximally to the crest. At the fore part of the urethral crest is an elevation, the *colliculus seminalis*, on which are the orifice of the prostatic utricle and the openings of the ejaculatory ducts. The *prostatic utricle* or *uterus masculinus* forms a cul-de-sac about 6 mm. long, which runs upwards and backwards in the substance of the prostate behind the middle lobe. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It is developed from the united lower ends of the Møllerian ducts, and is therefore homologous with the uterus and vagina of the female. The ejaculatory ducts are described on p. 1170.

The membranous portion is the shortest, least dilatable, and, with the exception of the external orifice, the narrowest part of the urethra. It runs downwards and forwards, with a slight anterior concavity, from the prostate to the bulb of the urethra, perforating the urogenital diaphragm about 2.5 cm. below and behind the *punctum symphyseum*. The hinder part of the urethral bulb lies in apposition with the anterior bands of the urogenital diaphragm, but its upper portion diverges somewhat from this plane; the anterior wall of the membranous urethra is thus protected by a short distance in front of the urogenital diaphragm, and measures about 2 cm. in length, while the posterior wall, which is between the two bands of the diaphragm is only 1.25 cm. long. The membranous portion of the urethra is completely surrounded by the fibres of the *bulbospongiosus* and *ischio-cavernosus* muscles. In front of it the deep dorsal vein of the penis crosses the pelvis between the transverse ligament of the

FIG. 1077.—The male urethra laid open on its anterior (upper) surface.

pelvis and the arcuate pubic ligament; on either side near its termination are the bulbo-urethral glands. The junction of the membranous and cavernous portions of the urethra is the lowest part of the tube.

The cavernous portion is contained in the corpus cavernosum urethrae. It is about 15 cm. long, and extends from the end of the membranous portion to the external urethral orifice. Commencing below the inferior fascia of the urogenital diaphragm, it passes forwards and upwards to the front of the symphysis pubis; and then, in the flaccid condition of the penis, it bends downwards and forwards. It is narrow, with a uniform diameter of about 6 mm. in the body of the penis; it is dilated behind, within the bulb, and again anteriorly within the glans penis, where it forms the *fossa navicularis urethrae*.

The external urethral orifice is the most contracted part of the urethra; it is a vertical slit, about 6 mm. long, bounded on either side by two small labia.

The lining membrane of the urethra, especially on the floor of the cavernous portion, presents the orifices of numerous mucous glands and follicles situated in the submucous tissue, and named the *urethral glands* (Littre). Besides these there are a number of small pit-like recesses, or *lacunae*, of varying sizes. Their orifices are directed forwards, and may intercept the point of a catheter in its passage along the canal. One lacuna, larger than the rest, is situated on the upper surface of the fossa navicularis; it is called the *lacuna magna*. The bulbo-urethral glands open into the cavernous portion about 2.5 cm. in front of the urogenital diaphragm.

Structure.—The urethra is composed of mucous membrane, supported by a submucous tissue which connects it with the various structures through which it passes.

The mucous coat forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, and externally with the skin covering the glans penis; it is prolonged into the ducts of the glands which open into the urethra, viz. the bulbo-urethral glands and the glands of the prostate; and into the ductus deferentes and vesiculae seminales, through the ejaculatory ducts. In the cavernous and membranous portions the mucous membrane is arranged in longitudinal folds when the tube is empty. Small papillae are found upon it, near the external urethral orifice; its epithelial lining is of the columnar variety except near the external orifice, where it is squamous and stratified.

The submucous tissue consists of a vascular erectile layer; outside this is a layer of unstripped muscular fibres, arranged in a circular direction, which separates the mucous membrane and submucous tissue from the tissue of the corpus cavernosum urethrae.

The lymphatic vessels of the urethra are described on p. 784.

Applied Anatomy.—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perineum and the history of the accident, will point to the nature of the injury. Rupture of the urethra is due in other cases to the perforation of a peri-urethral abscess. Extravasation of urine most frequently takes place into the perineum in front of the inferior fascia of the urogenital diaphragm, i.e. under the fascia of Colles. Both these layers of fascia are attached firmly to the ischiopubic rami. It is clear, therefore, that when extravasation of fluid takes place between them, it cannot pass backwards, because the two layers are continuous with each other around the Transversi perinei superficiales; it cannot extend laterally, on account of the connexion of these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the urogenital diaphragm, and, therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forwards into the areolar tissue of the scrotum and penis, and thence on to the anterior wall of the abdomen.

Gonorrhoea is an acute and very prevalent inflammatory infection of the mucous membrane of the urethra. The causative organisms (gonococci) pass through the mucous membrane into the submucous tissue, and most serious complications and results may follow. In most cases the disease remains limited to the part of the urethra in front of the urogenital diaphragm, but in some (about 10 per cent.) the 'posterior urethra' becomes involved in the process, leading to an inflammation of the openings of the prostatic follicles. Such a condition is apt to continue as a very chronic form of prostatitis, and in many cases the infection will spread along the ductus deferentes, giving rise to epididymitis.

The anatomy of the urethra is of considerable importance in connexion with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatation, so that, excepting through the external urethral orifice, an instrument corresponding to 18 English gauge (20 French) can usually be passed without

damage. The external orifice of the urethra is not so dilatable, and therefore may require slitting. A recognition of this dilatability caused Bigelow to modify very considerably the operation for crushing a stone in the bladder. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal, as otherwise it is very liable to enter one of the lacunæ.

Stricture of the urethra is a disease of very common occurrence, and is generally situated in the cavernous part of the urethra, just in front of the membranous portion but in a very considerable number of cases in the antescrotal part of the canal. The stricture usually results from the contraction of inflammatory products in the submucous tissue, the result, in the vast majority of all cases, of a prolonged gleet following gonorrhoea. Urethral stricture, however, follows rupture of that tube resulting from falls on the perineum, and in this variety is very dense, and is a most unsatisfactory condition with regard to treatment. Congenital stricture is also occasionally met with, and in such cases multiple strictures may be present throughout the whole length of the cavernous portion.

Congenital defects of the urethra occur occasionally. The one most frequently met with is where there is a cleft on the floor of the urethra owing to an arrest of union in the middle line. This is known as *hypospadias*, and the cleft may vary in extent. The simplest and by far the most common form is where the deficiency is confined to the glans penis. The urethra ends at the point where the extremity of the prepuce joins the body of the penis, in a small valve-like opening. The prepuce is also cleft on its under surface and forms a sort of hood over the glans. There is a depression on the glans in the position of the normal meatus. This condition produces no disability and requires no treatment. In more severe cases the cavernous portion of the urethra is cleft throughout its entire length, and the opening of the urethra is at the point of junction of the penis and scrotum. The under surface of the penis in the middle line presents a furrow lined by a moist mucous membrane, on either side of which is often more or less dense fibrous tissue stretching from the glans to the opening of the urethra, which prevents complete erection taking place. Great discomfort is induced during micturition, and sexual connexion is impossible. The condition may be remedied by a series of plastic operations. The worst form of this condition is where the urethra is deficient as far back as the perineum, and the scrotum is cleft. The penis is small and bound down between the two halves of the scrotum, so as to resemble a hypertrophied clitoris. The testes are often retained in the abdomen. The condition of parts, therefore, very much resembles the external organs of generation of the female, and many children the victims of this malformation have been brought up as girls. The halves of the scrotum, deficient of testes, resemble the labia, the cleft between them looks like the orifice of the vagina, and the diminutive penis is taken for an enlarged clitoris. There is no remedy for this condition.

A much more uncommon form of malformation is where there is an apparent deficiency of the upper wall of the urethra; this is named *epispadias*. The deficiency may vary in extent; when it is complete the condition is associated with extroversion of the bladder (p. 1159). In less extensive cases, where there is no extroversion, there is an infundibuliform opening into the bladder. The penis is usually dwarfed and turned upwards, so that the glans lies over the opening.

THE FEMALE URETHRA (fig. 1074)

The female urethra is about 4 cm. long and 6 mm. in diameter. It begins at the internal urethral orifice of the bladder, and runs downwards and forwards behind the symphysis pubis, imbedded in the anterior wall of the vagina. It perforates the urogenital diaphragm and ends at the external urethral orifice, an anteroposterior slit which has rather prominent margins, and is situated directly in front of the vaginal opening and about 2.5 cm. behind the glans clitoridis. Except during the passage of fluid the anterior and posterior walls of the urethra are in apposition, and the lining membrane is thrown into longitudinal folds, one of which, placed on the posterior wall of the canal, is termed the urethral crest. Many small urethral glands open into the urethra.

Structure.—The urethra consists of three coats: muscular, erectile, and mucous.

The muscular coat is continuous with that of the bladder; it extends the whole length of the tube, and consists of circular fibres. In addition to this, between the superior and inferior fasciæ of the urogenital diaphragm, the female urethra is surrounded by the sphincter urethrae membranaceus, as in the male.

A thin layer of spongy erectile tissue, containing a plexus of large veins, intermixed with bundles of unstriated muscular fibres, lies immediately beneath the mucous coat.

The mucous coat is pale; it is continuous externally with that of the vulva, and internally with that of the bladder. It is lined by stratified squamous epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

THE MALE GENITAL ORGANS

The male genital organs include the *testes* and *epididymis*, the *ductus deferentes*, the *vesiculæ seminales*, the *ejaculatory ducts*, and the *penis*, together with the following accessory structures, viz. the *prostate* and the *bulbo-urethral glands*.

THE TESTES

The *testes*, the reproductive glands in the male, are suspended in the scrotum by the spermatic cords, the left testis hanging somewhat lower than its fellow. The average dimensions of the testis are from 4 cm. to 5 cm. in

FIG. 1078.—The right testis, exposed by laying open the tunica vaginalis.

length, 2.5 cm. in breadth, and 3 cm. in the anteroposterior diameter; its weight varies from 10.5 gm. to 14 gm. Each testis is of an oval form (fig. 1078), compressed laterally, and has an oblique position in the scrotum; the upper extremity is directed forwards and a little lateralwards; the lower, backwards and a little medialwards; the anterior convex border looks forwards and downwards; the posterior or straight border, to which the spermatic cord is attached, backwards and upwards.

The anterior border and lateral surfaces, as well as both extremities of the testis, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border receives only a partial investment from that membrane. Lying upon the lateral edge of this posterior border is the *epididymis*.

Epididymis.—The epididymis consists essentially of a tortuous canal which forms the first part of the efferent duct of the testis. This canal is folded on itself and tightly packed into the form of a long, narrow, flattened body attached to the lateral part of the posterior border of the testis. It consists of a central portion, or *body*; an upper enlarged extremity, the *head* (*glans major*); and a lower pointed extremity, the *tail* (*glans minor*). The head is intimately connected with the upper end of the testis by means of the efferent ductules of the gland; the tail is connected with the lower end by cellular tissue, and a reflection of the tunica vaginalis. The lateral surfaces of the head and tail of the epididymis are free and covered by the tunica vaginalis.

The body is also completely invested by it, except at its posterior border; whilst between the body of the epididymis and the lateral surface of the testis is a pouch, named the *sinus of the epididymis* (digital fossa).

Appendages of the testis and epididymis.—On the upper extremity of the testis, just beneath the head of the epididymis, is a minute oval, sessile body, the *appendix of the testis* (hydatid of Morgagni); it is the remnant of the upper end of the Müllerian duct. On the head of the epididymis is a second small stalked appendage (sometimes duplicated); it is named the *appendix of the epididymis* (pedunculated hydatid), and is usually regarded as a detached efferent duct.

The testis is invested by three tunics: the tunica vaginalis, tunica albuginea, and tunica vasculosa.

The tunica vaginalis is the lower portion of the saccus vaginalis of the peritoneum which, in the foetus, preceded the descent of the testis from the abdomen into the scrotum. After the testis has reached the scrotum the upper part of the saccus vaginalis, viz. from the abdominal inguinal ring to within a short distance of the testis, contracts and undergoes obliteration. The lower portion remains as a shut sac, which invests the surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and a parietal lamina.

The *visceral lamina* covers the greater part of the testis and epididymis. It lines the sinus of the epididymis and passes as two folds, one from the head and the other from the tail of the epididymis, to the testis; these folds are termed the *superior and inferior ligaments of the epididymis*. From the posterior border of the testis it is reflected on to the internal surface of the scrotum.

The *parietal lamina* is more extensive than the visceral, extending upwards for some distance in front and on the medial side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal laminae constitutes the cavity of the tunica vaginalis.

The obliterated portion of the saccus vaginalis may frequently be seen as a fibrous thread in the areolar tissue in front of the spermatic cord; sometimes this thread may be traced from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it is lost on the spermatic cord. In some cases the upper part of the saccus vaginalis is not obliterated, and the peritoneal cavity then communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia (p. 1125). In other cases the upper part of the saccus vaginalis may persist as a minute canal leading from the peritoneal cavity to that of the tunica vaginalis.

The tunica albuginea forms a fibrous covering for the testis. It is a dense membrane of a bluish-white colour, composed of interlacing bundles of white fibrous tissue. It is covered by the tunica vaginalis, except at the head and tail of the epididymis, and along the posterior border of the testis, where the testicular vessels and nerves enter the gland. It is applied to the tunica vasculosa over the glandular substance of the testis, and, at its posterior border, is reflected into the interior of the gland, forming an incomplete vertical septum, called the *mediastinum testis* (*corpus Highmori*).

The *mediastinum testis* extends from the upper to near the lower extremity of the gland, and is wider above than below. From its front and sides numerous

FIG. 1079.—A vertical section of the testis, to show the arrangement of the ducts. (Diagrammatic.)

imperfect septa (*septula testis*) are given off, which radiate towards the surface of the testis, and are attached to the deep aspect of the tunica albuginea. They incompletely divide the testis into a number of cone-shaped lobules (*lobuli testis*). The bases of the lobules are at the surface of the testis, and their apices converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

The *tunica vasculosa* is the vascular layer of the testis, consisting of a plexus of blood-vessels held together by delicate areolar tissue. It lines the tunica albuginea and clothes the *septula testis*, and therefore forms an investment to all the lobules of the testis.

Structure.—The glandular structure of the testis consists of the *lobuli testis* (fig. 1079). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the testis being larger and longer. Each lobule consists of from one to three, or more, minute convoluted

FIG. 1080.—A transverse section through a tubule of the testis of a rat. $\times 250$.

tubes, the *tubuli seminiferi contorti*. When the tubules have been unravelled by careful dissection under water, they are seen to commence either by free caecal ends or by anastomotic loops. They are supported by loose connective tissue which contains here and there groups of *interstitial cells* containing yellow pigment granules. The total number of tubules is estimated by Lauch at 840, and the average length of each is 70 cm. to 80 cm. Their diameter varies from 0.12 mm. to 0.3 mm. The tubules are pale in colour in early life, but in old age they acquire a deep yellow tinge from containing much fatty matter. Each tubule (fig. 1080) consists of a basement layer formed of laminated connective tissue containing numerous elastic fibres, with flattened cells between the layers, and covered externally by a layer of flattened epithelioid cells. Within the basement membrane are epithelial cells arranged in three irregular layers. 1. An outer layer of cubical cells, with small nuclei; some of these enlarge to become *spermatogonia*. The nuclei of some of the spermatogonia may be seen to be in process of indirect division (p. 2), and in consequence of this, daughter cells are formed, which constitute the second zone. 2. Larger polyhedral cells, with clear nuclei, arranged in two or three layers; these are the *intermediate cells* or *spermatocytes*. Most of these cells are in a condition of indirect division, and the cells which result from this division form those of the next layer. 3. The third layer of cells consists of the *spermatids*, each of which becomes a *spermatozoon*. The spermatids are small polyhedral cells, the nucleus of each containing half the usual number of chromosomes. The changes which occur during the conversion of the spermatids into spermatozoa are described on pp. 45, 46 and illustrated in fig. 65, p. 46. In addition to these three layers of cells others, termed the *supporting cells*, or *cells of Sertoli* are seen. They are elongated and columnar, and project inwards from the basement membrane towards the lumen of the tube. As development of the spermatozoa proceeds, the latter group themselves upon the inner extremities of the supporting cells. Ultimately the spermatozoa are liberated and set free. The structure of the spermatozoa is described on p. 44.

In the apices of the lobules, the tubules become less convoluted, assume a nearly straight course, and unite together to form from twenty to thirty larger straight ducts, of about 0.5 mm. in diameter, called *tubuli seminiferi recti* (fig. 1079).

The *tubuli seminiferi recti* enter the fibrous tissue of the mediastinum, and pass upwards and backwards, forming, in their ascent, a close network of anastomosing tubes which are merely channels in the fibrous stroma, lined by flattened epithelium, and having no proper walls; this network is named the *rete testis*. At the upper end of the mediastinum, the vessels of the rete testis terminate in from twelve to twenty ducts, the *ductuli efferentes testis*; they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; they then become enlarged and exceedingly convoluted, and form a series of conical masses, the *lobules of the epididymis (coni vasculosi)*, which together constitute the head of the epididymis. Each lobule consists of a single convoluted duct, from 15 cm. to 20 cm. in length. Opposite the bases of the lobules the canals open into a single duct, which constitutes, by its complex convolutions, the body and tail of the *epididymis*. When the convolutions are unravelled, this tube measures upwards of 6 metres in length; it increases in diameter and thickness as it approaches the tail of the epididymis where it becomes the *ductus deferens*. The convolutions are held together by fine areolar tissue, and by bands of fibrous tissue.

FIG. 1081.--A section of the epididymis of a guinea-pig. $\times 255$.

The ductuli efferentes and the tube of the epididymis have walls of considerable thickness, on account of the presence in them of muscular tissue which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium (fig. 1081).

Applied Anatomy.—The descent of the testis may be arrested. It may be retained in the abdomen; or it may be arrested at the abdominal inguinal ring, or in the inguinal canal; or it may just pass out of the subcutaneous inguinal ring without finding its way to the bottom of the scrotum. When retained in the abdomen it gives rise to no signs or symptoms, other than the absence of the testis from the scrotum. When it is retained in the inguinal canal it is subjected to pressure and may become inflamed and painful. The retained testis is probably functionally useless; so that a man in whom both testes are retained (*anorchism*) is sterile, though he may not be impotent. The absence of one testis is termed *monorchism*. When a testis is retained in the inguinal canal it is often complicated with a congenital hernia, the saccus vaginalis of the peritoneum not being obliterated. The testis may descend through the inguinal canal, but may miss the scrotum and assume some abnormal position. The most common form is where it comes to rest in the perineum. This is known as *perineal ectopia testis*. When the testis occupies an abnormal position it is very common to find concurrently a congenital hernia or a patent saccus vaginalis.

The testis may be inverted within the scrotum so that its posterior or attached border is directed forwards and the tunica vaginalis is situated behind. Should a hydrocele occur, and tapping be resorted to, the trocar may be thrust into the testis, if care be not taken beforehand to ascertain the position of the gland.

A number of instances of torsion of the spermatic cord, resulting in acute strangulation of the testis, have been recorded. In some it has been attributed to a strain or twist, and in several patients the condition has been associated with a late descent of the organ. Symptoms of this condition closely simulate those of a strangulated hernia. In consequence of the torsion the circulation is partly arrested and the organ swells and

becomes acutely painful, and the condition may be accompanied with shock and vomiting. Gangrene of the testis, however, rarely follows, and the condition if left without operation, ends in atrophy of the organ. Torsion of the body of the testis also sometimes occurs within the tunica vaginalis in those cases in which a persistent mesorchium is present.

Fluid collections of a serous character are frequently found in the scrotum. To these the term *hydrocele* is applied. The most common form is the ordinary *vaginal hydrocele*, in which the fluid is contained in the sac of the tunica vaginalis. In another form, the *congenital hydrocele*, the fluid is in the sac of the tunica vaginalis, but this sac communicates with the general peritoneal cavity owing to the non-obliteration of the upper part of the *saccus vaginalis*. A third variety, known as an *infantile hydrocele*, occurs in those cases where the *saccus vaginalis* is obliterated only, at or near the abdominal inguinal ring. It resembles the vaginal hydrocele, except as regards its shape, the collection of fluid extending up the cord into the inguinal canal. Fourthly, the *saccus vaginalis* may be obliterated both at the abdominal inguinal ring and above the epididymis, leaving a central unobliterated portion, which may become distended with fluid, giving rise to a condition known as the *encysted hydrocele of the cord*.

Encysted hydrocele of the epididymis or *spermatocele* is the name given to a cyst found in connexion with the head of the epididymis. Among its contents are found a varying number of spermatozoa, and it is probably a retention cyst of one of the tubules.

The testis requires removal for malignant or tuberculous disease, in cases of large *hernia testis*, and in some instances of incompletely descended or misplaced testis. Castration is in most cases best carried out by the 'high' operation, an incision being made through the skin and fascia in the region of the subcutaneous inguinal ring. The testis, with its deeper coverings, is pushed up into the wound and separated from the scrotal tissues. The cord is then isolated, and an aneurysm needle, armed with a ligature, passed through it, as high as is thought necessary, and the cord tied and divided. In cases of malignant and tuberculous disease, it is desirable to open the inguinal canal and tie the cord as near the abdominal ring as possible. When removing the testis in this manner the tunica vaginalis is not opened and its folds of reflection to the scrotal tissues do not need division. The whole of the tunica vaginalis is thus removed with the cord and its coverings.

Acute inflammation of the testis, or *orchitis*, is common in gonorrhœa: a chronic fibrosing form of orchitis is frequent in syphilis, and leads to shrinkage and hardening of the testis. In *tabes dorsalis* the testis often becomes quite insensitive to pressure, which, in the healthy adult, readily produces a severe and peculiar sickening sensation.

THE DUCTUS DEFERENS

The ductus deferens (*vas deferens*) is the continuation of the canal of the epididymis. Commencing at the lower part of the tail of the epididymis, it is at first very tortuous, but gradually becoming less twisted it ascends along the posterior border of the testis and medial side of the epididymis, and then runs upwards in the posterior part of the spermatic cord, and traverses the inguinal canal to the abdominal inguinal ring. Here it separates from the other structures of the cord, curves round the lateral side of the inferior epigastric artery, and ascends for about 2.5 cm. in front of the external iliac artery. It is next directed backwards and slightly downwards, and, crossing the external iliac vessels obliquely, enters the pelvic cavity, where it is continued backwards between the peritoneal membrane and the lateral wall of the pelvis, and on the medial side of the obliterated umbilical artery, the obturator nerve and vessels, and the vesical vessels. It then crosses in front of the ureter (fig. 1082), and, reaching the medial side of this tube, bends at an acute angle, and runs medialwards and slightly forwards between the fundus of the bladder and the upper end of the seminal vesicle. Reaching the medial side of the seminal vesicle, it is directed downwards and medialwards in contact with it, and gradually approaches the opposite ductus. Here it lies between the fundus of the bladder and the rectum, where it is enclosed, together with the seminal vesicle, in a sheath derived from the rectovesical portion of the fascia endopelvina. Lastly, it passes downwards to the base of the prostate, and is joined at an acute angle by the duct of the seminal vesicle to form the ejaculatory duct, which traverses the prostate behind its middle lobe and opens into the prostatic portion of the urethra, close to the orifice of the prostatic utricle. The ductus deferens presents a hard and cord-like sensation to the fingers, and is of cylindrical form. Its walls are thick, and its canal is the greater part of its extent is of extremely small calibre. At the fundus of the bladder it becomes dilated and tortuous, and this portion is termed the *ampulla*; its

terminal portion, which joins the ejaculatory duct, is again greatly diminished in calibre.

Ductuli aberrantes.—A long narrow tube, the *ductulus aberrans inferior* (was aberrans of Haller), is frequently found connected with the lower part of the canal of the epididymis, or with the commencement of the ductus deferens. Its length, when it is uncoiled, varies from 5 cm. to 35 cm., and it may be dilated towards its blind extremity, or may be of uniform diameter throughout. Its structure is similar to that of the ductus deferens. Occasionally it is found unconnected with the epididymis. A second tube, the *ductulus aberrans superior*, occurs in the head of the epididymis, and is connected with the rete testis.

Paradidymis (organ of Giralès).—This term is applied to a small collection of convoluted tubules, situated in front of the lower part of the spermatic cord above the head of the epididymis. These tubes are lined with columnar ciliated epithelium, and probably represent the remains of a part of the Wolffian body.

Structure.—The ductus deferens consists of three coats: (1) an external or areolar coat; (2) a muscular coat, which in the greater part of the tube consists of two layers of unstriated muscular fibres: an outer, longitudinal in direction, and an inner, circular; but at the commencement of the ductus there is a third layer, consisting of longitudinal fibres, and placed between the circular stratum and the mucous membrane; (3) an internal, or mucous coat, which is pale, and arranged in longitudinal folds. The mucous coat is lined by columnar epithelium which is non-ciliated throughout the greater part of the tube; a variable portion of the testicular end of the tube is lined by two strata of columnar cells, those of the superficial layer being ciliated.

THE VESICULÆ SEMINALES AND EJACULATORY DUCTS

The *vesiculæ seminales* (fig. 1082) are two sacculated pouches, placed between the fundus of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testes.

FIG. 1082.—The fundus of the bladder with the vesiculæ seminales, &c.

Each vesicle is somewhat pyramidal in form, the broad end being directed backwards, upwards, and lateralwards. It is usually about 5 cm. long, but varies in size, not only in different individuals, but also in the same individual on the two sides. Each vesicle consists of a single tube, coiled upon itself, and giving off several irregular cæcal diverticula (fig. 1083); the separate coils, as well as the diverticula, are connected together by fibrous tissue. When

uncolled, the tube is about the diameter of a quill, and varies in length from 10 cm. to 15 cm.; it ends above in a cul-de-sac; its lower extremity becomes constricted into a narrow straight duct, which joins with the corresponding ductus deferens to form the ejaculatory duct. The *anterior surface* is in contact with the fundus of the bladder, extending from near the termination of the ureter to the base of the prostate. The *posterior surface* rests upon the rectum,

from which it is separated by the rectovesical fascia. The vesicles diverge from each other above, and are in relation with the ductus deferentes and the terminations of the ureters, and are partly covered by peritoneum; each is enveloped in a dense fibromuscular sheath. Along the medial margin of each vesicle runs the ampulla of the ductus deferens.

FIG. 1083.—The vesiculæ seminales and the ampullæ of the ductus deferentes, seen from the front. The anterior walls of the left ampulla, left seminal vesicle, and prostatic urethra have been cut away.

Structure.—The vesiculæ seminales are composed of three coats: an *external or arcolar coat*; a *middle or muscular coat*, thinner than in the ductus deferens and arranged in two layers, an outer longitudinal and an inner circular; an *internal or mucous coat*, which is pale, of a whitish-brown colour, and presents a delicate reticular structure. The epithelium is columnar,

and in the diverticula goblet-cells are present, the secretion of which is added to the seminal fluid.

Vessels and Nerves.—The *arteries* supplying the vesiculæ seminales are derived from the middle and inferior vesical, and the middle hæmorrhoidal arteries. The *veins* and *lymphatics* accompany the arteries. The *nerves* are derived from the pelvic plexuses.

Applied Anatomy.—The vesiculæ seminales are often the seat of an extension of the disease in cases of tuberculosis of the testis, and should always be examined from the rectum, before deciding to perform castration in this affection. They also become affected in chronic posterior urethritis of gonorrhæal origin.

The **ejaculatory ducts** (fig. 1083) are two in number, one on either side of the middle line. Each is formed by the union of the duct of the vesicula seminalis with the ductus deferens, and is nearly 2 cm. long. They commence at the base of the prostate, run forwards and downwards between the middle and lateral lobes, pass along the sides of the prostatic utricle, and end on the colliculus seminalis in slit-like orifices on or just within the margins of the opening of the prostatic utricle (p. 1161). The ducts diminish in size, and also converge, towards their terminations.

Structure.—The coats of the ejaculatory ducts are extremely thin. They are: an *outer fibrous layer*, which is almost entirely lost after the entrance of the ducts into the prostate; a *layer of muscular fibres*, consisting of a thin outer circular, and an inner longitudinal layer; and *mucous membrane*.

THE SPERMATIC CORD AND ITS COVERINGS

When the testis descends through the abdominal wall into the scrotum, it drags its excretory duct, and its vessels and nerves with it. These structures meet at the abdominal inguinal ring and together form the *spermatic cord* (*funiculus spermaticus*) which suspends the testis in the scrotum, and extends from the abdominal inguinal ring to the posterior border of the testis. The left spermatic cord is rather longer than the right, and consequently the left testis hangs somewhat lower than its fellow.

The spermatic cord traverses the inguinal canal (p. 465) and in so doing is covered by the different layers which form the abdominal wall. These coverings extend downwards into the wall of the scrotum and are named, from within outwards, the *infundibuliform*, *cremasteric* and *intercrural fasciæ*.

The *infundibuliform fascia* is a thin layer which loosely invests the cord, and is derived from the *transversalis fascia* (p. 465).

The *cremasteric fascia* consists of a number of muscular fasciculi, united to one another by areolar tissue; the muscular fasciculi constitute the *Cremaster* and are continuous with the *Obliquus internus abdominis* (p. 461).

The *intercrural fascia* (*external spermatic fascia*) is a thin fibrous membrane continuous above with the tendon of the *Obliquus externus abdominis*, and prolonged downwards from the crura of the subcutaneous inguinal ring (p. 458).

Structure of the spermatic cord.—The spermatic cord is composed of arteries, veins, lymphatics, nerves, and the ductus deferens, connected together by areolar tissue.

The *arteries* of the spermatic cord are: the testicular artery, the external spermatic artery, and the artery to the ductus deferens.

The *testicular artery*, a branch of the abdominal aorta, escapes from the abdominal cavity at the abdominal inguinal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the subcutaneous inguinal ring into the scrotum. It then descends to the testis, and, becoming tortuous, divides into several branches, two or three of which accompany the ductus deferens and supply the epididymis, anastomosing with the artery of the ductus deferens; the others supply the substance of the testis.

The *external spermatic artery* (*cremasteric artery*) is a branch of the inferior epigastric artery. It supplies the coverings of the spermatic cord, and anastomoses with the testicular artery.

The *artery of the ductus deferens*, a branch of the superior vesical artery, is a long slender vessel which accompanies the ductus deferens, ramifying upon its coats, and anastomosing with the testicular artery near the testis.

The *testicular veins* emerge from the back of the testis, and receive tributaries from the epididymis: they unite and form a convoluted plexus, the *plexus pampiniformis*, which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend in front of the ductus deferens; below the subcutaneous inguinal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the abdominal inguinal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava, at an acute angle, and on the left side into the left renal vein, at a right angle.

The *lymphatic vessels* of the testis are described on p. 734.

The *nerves* are the spermatic plexus of the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the ductus deferens.

THE SCROTUM

The *scrotum* is a cutaneous pouch containing the testes and parts of the spermatic cords, and placed below the pubic symphysis in front of the upper parts of the thighs. It is divided on its surface into two lateral portions by a ridge, or *raphe*, which is continued forwards to the under surface of the penis, and backwards along the middle line of the perinæum to the anus; the left portion hangs lower than the right, in correspondence with the greater length of the left spermatic cord. The external appearance varies under different circumstances: thus, under the influence of warmth, and in old and debilitated persons, it is elongated and flaccid; but, under the influence of cold, and in the young and robust, it is short, corrugated, and closely applied to the testes. It consists of the skin and the dartos tunic, together with the intercrural, cremasteric and infundibuliform fasciæ, already described in connexion with the spermatic cord. Within the infundibuliform fascia is the parietal lamina of the tunica vaginalis (fig. 1084).

The *skin* is very thin, of a brownish colour, and generally thrown into folds or rugæ. It is provided with sebaceous follicles, the secretion of which has a peculiar odour, and is beset with thin, scattered, crisp hairs, the roots of which are visible through the skin.

The *dartos tunic* is a thin layer of non-stripped muscular fibres, continuous, around the base of the scrotum, with the superficial fascia of the groin and

of the perinæum. It sends inwards a septum, which connects the raphe to the under surface of the root of the penis, and divides the scrotal pouch into two cavities for the testes. The dartos tunic is closely united to the skin, but is connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility

Vessels and Nerves.—The *arteries* supplying the scrotum are : the superficial and deep external pudendal branches of the femoral artery, the superficial perineal branch of the internal pudendal artery, and the cremasteric branch from the inferior epigastric artery. The *veins* follow the course of the corresponding arteries. The *lymphatics* end in the inguinal lymph-glands. The *nerves* are the ilio-inguinal and lumbo-inguinal branches of the lumbar plexus, the two posterior scrotal branches of the perineal nerve, and the pudendal branch of the posterior femoral cutaneous nerve.

FIG. 1084.—A transverse section through the left half of the scrotum and the left testis. The sac of the tunica vaginalis is represented in a distended condition. (Diagrammatic.) (Delépine.)

Applied Anatomy.—The scrotum forms an admirable covering for the protection of the testes. These bodies, lying suspended and loose in the cavity of the scrotum and surrounded by serous membrane, are capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue, the scrotum becomes greatly enlarged in cases of œdema, to which this part is especially liable as a result of its dependent position. The scrotum is occasionally the seat of epithelioma; this is no doubt due to the rugæ on its surface, which favour the lodgment of dirt, and this, producing irritation, is the exciting cause of the disease, which is especially common in chimney-sweeps from the lodgment of soot. The disease is very much less common than it used to be; this is probably due to the better hygienic conditions of the working classes. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue, large extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local blood-letting from this part is judged to be desirable. The muscular fibres in the dartos tunic cause contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and are of assistance in keeping the edges together, and covering the exposed parts.

THE PENIS

The penis is a pendulous organ suspended from the front and sides of the pubic arch and containing the greater part of the urethra. In the flaccid condition it is cylindrical in shape, but when erect assumes the form of a triangular prism with rounded angles, one side of the prism forming the dorsum. It is composed of three cylindrical masses of cavernous tissue bound together by fibrous tissue and covered with skin. Two of the masses are placed side by side, and are known as the *corpora cavernosa penis*; the third is median in position and beneath the other two; it is traversed by the cavernous part of the urethra, and is termed the *corpus cavernosum urethræ* (figs. 1085, 1086).

The *corpora cavernosa penis* form the greater part of the substance of the penis. Throughout the anterior three-fourths of their extent they lie in apposition with one another, separated only by the septum of the penis; behind, they diverge in the form of two tapering processes, known as the *crura*, which are firmly connected to the rami of the pubic arch. Traced from behind forwards each crus begins as a blunt-pointed process in front of the tuberosity of the ischium. Just before it meets its fellow it presents a slight enlargement, named by Kobelt the *bulb of the corpus cavernosum penis*. Beyond this point the crus undergoes a constriction and merges into the corpus cavernosum proper, which retains a uniform diameter to its anterior end. Each corpus cavernosum penis ends abruptly in a rounded extremity some distance from the point of the penis.

The *corpora cavernosa penis* are surrounded by a strong fibrous envelope consisting of superficial and deep fibres. The superficial fibres are longitudinal in direction, and form a single tube which encloses both corpora; the deep fibres are arranged circularly round each corpus, and form by their junction in the median plane the *septum of the penis*. This septum is thick and complete behind, but is imperfect in front, where it consists of a series of vertical bands arranged like the teeth of a comb; it is therefore named the *septum pectiniforme*.

The *corpus cavernosum urethræ* (*corpus spongiosum*) contains the cavernous part of the urethra. Behind, it is expanded to form the urethral bulb, and lies in apposition with the inferior fascia of the urogenital diaphragm, from which it receives a fibrous investment. The urethra enters the bulb nearer to the upper than to the lower surface. On the lower surface of the bulb there is a median sulcus, from which a thin fibrous septum projects into the substance of the bulb and divides it imperfectly into two lateral lobes or *hemispheres*.

FIG. 1085.—The constituent cavernous cylinders of the penis. The glans penis and the anterior part of the corpus cavernosum urethræ are detached from the corpora cavernosa penis and turned to one side.

The portion of the corpus cavernosum urethræ in front of the bulb lies in a groove on the under surface of the conjoined corpora cavernosa penis. It is cylindrical in form and tapers slightly from behind forwards. Its anterior end suddenly expands to form an obtuse cone, flattened from above downwards. This expansion, termed the *glans penis*, is moulded on the rounded ends of the corpora cavernosa penis, extending farther on their upper than on their lower surfaces. Near the summit of the glans is the slit-like vertical external urethral orifice. The circumference of the base of the glans forms a rounded projecting border, the *corona glandis*, overhanging a deep *retroglandular sulcus*, behind which is the *neck* of the penis.

For descriptive purposes it is convenient to divide the penis into three regions: the root, the body, and the extremity.

The *root* of the penis is triradiate in form, consisting of the diverging crura, one on either side, and the median urethral bulb. Each crus is covered by the Ischiocavernosus, while the bulb is surrounded by the Bulbocavernosus.

FIG. 1086.—A transverse section through the penis.

The root of the penis lies in the perinæum between the inferior fascia of the urogenital diaphragm and the fascia of Colles. In addition to being attached to the fascia and the pubic rami, it is bound to the front of the symphysis pubis by the fundiform and suspensory ligaments. The fundiform ligament springs from the front of the sheath of the Rectus abdominis and the linea alba; it splits into two fasciculi which pass one on either side of the penis and unite below with the

septum of the scrotum. The upper fibres of the *suspensory ligament* pass downwards from the lower end of the linea alba, and the lower fibres from the symphysis pubis; together they form a strong fibrous band, which extends to the upper surface of the root of the penis, where it blends with the fibrous envelope of the corpora cavernosa penis.

The *body* extends from the root of the penis to the anterior end of the corpora cavernosa penis. In the body the corpora cavernosa are intimately bound to one another; a shallow groove which marks their junction on the upper surface lodges the deep dorsal vein of the penis, while a deeper and wider groove between them on the under surface contains the corpus cavernosum urethræ. The body is ensheathed by fascia, which is continuous above with the fascia of Scarpa and below with the dartos tunic of the scrotum and the fascia of Colles.

The *extremity* is formed by the glans penis, the expanded anterior end of the corpus cavernosum urethræ. It is separated from the body by the neck of the penis, which is overhung by the corona glandis.

The skin covering the penis is remarkable for its thinness, its dark colour, its looseness of connexion with the deeper parts of the organ, and its absence of adipose tissue. At the root of the penis it is continuous with the skin over the pubes, scrotum, and perinæum. At the neck of the penis it is folded upon itself to form the *prepuce* or *foreskin*, the internal layer of which is directly continuous, along the line of the neck, with the integument over the glans. Immediately behind the external urethral orifice it forms a small secondary reduplication, attached along the bottom of a depressed median raphe, which extends from the meatus to the neck; this fold is termed the *frenulum* of the prepuce. The integument covering the glans is continuous with the urethral mucous membrane at the urethral orifice. On the corona and neck there are numerous small *preputial glands* which secrete a sebaceous material of very peculiar odour and named the *smegma preputii*.

The prepuce covers a variable amount of the glans, and is separated from it by a potential sac—the *preputial sac*—which presents two shallow fossæ, one on either side of the frenulum.

Structure of the penis.—From the internal surface of the fibrous envelope of the corpora cavernosa penis, as well as from the sides of the septum, numerous bands or cords (*trabeculae*) arise, and cross the interior of the corpora cavernosa in all directions, subdividing them into a number of compartments, and giving the entire structure a spongy appearance (fig. 1086). These consist of white fibrous tissue, elastic fibres, and plain muscular fibres (fig. 1087). In them are contained numerous arteries and nerves. The component fibres which form the trabeculae are larger and stronger round the circumference than at the centres of the corpora cavernosa; they are also thicker behind than in front. The interspaces (*cavernous spaces*) are filled with blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins.

The fibrous envelope of the corpus cavernosum urethrae is thinner, whiter in colour, and more elastic than that of the corpora cavernosa penis. The trabeculae are more delicate, nearly uniform in size, and the meshes between them are smaller than in the corpora cavernosa penis. The envelope of the corpus cavernosum urethrae is formed partly of unstriated muscular fibres, and a layer of the same tissue surrounds the canal of the urethra.

Vessels and Nerves.—The arteries bringing the blood to the cavernous spaces are the deep arteries of the penis and branches from the dorsal arteries of the penis, which perforate the fibrous capsule, along the upper surface, especially near the front part of the organ. On entering the cavernous structure the arteries divide into branches, which are supported and enclosed by the trabeculae. Some of these arteries end in a capillary network, the branches of which open directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller *helicine arteries*. They open into the spaces, and from them are also given off small capillary branches to supply the trabecular structure. They are most abundant in the posterior parts of the corpora cavernosa.

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the penis to form the deep dorsal vein: others pass out on the upper surface of the corpora cavernosa and join the same vein; some emerge from the under surface of the corpora cavernosa penis and, receiving branches from the corpus cavernosum urethrae, wind round the sides of the penis to end in the deep dorsal vein; but the greater number pass out at the root of the penis and join the prostatic plexus.

The *nerves* are derived from the pudendal nerve and the pelvic plexuses. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and many of them end in peculiar end-bulbs (p. 1006).

Applied Anatomy.—The penis occasionally requires removal for malignant disease. Removal of the antescrotal portion is usually all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the pubic and ischial rami. The former operation is performed by cutting through the corpora cavernosa penis from the dorsum, and then separating the corpus cavernosum urethrae from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which might otherwise take place. The vessels which require to be ligatured are the deep and the dorsal arteries of the penis, and the artery of the septum. When the entire organ requires removal, the patient is placed in the lithotomy position, and an incision is made through the skin and subcutaneous tissue round the root of the penis, and carried down through the median line of the scrotum as far as the perineum. The halves of the scrotum are then separated from each other, and, a catheter having been introduced into the bladder as a guide, the corpus cavernosum urethrae below the urogenital diaphragm is separated from the corpora cavernosa penis and divided, the catheter having been withdrawn. The suspensory ligament is now severed and the crura separated from the bone with a periosteum scraper. The membranous portion of the

urethra, which has not been removed, is attached to the skin at the posterior extremity of the incision in the perinæum. The remainder of the wound is closed, free drainage being provided for.

THE PROSTATE

The prostate (fig. 1082) is a firm, partly glandular and partly muscular body, surrounding the commencement of the urethra. It is situated in the pelvic cavity, behind the lower part of the symphysis pubis, and the superior fascia of the urogenital diaphragm, and in front of the rectum. It is about the size of a chestnut and somewhat conical in shape, and presents for examination a base, an apex, a posterior, an anterior, and two lateral surfaces.

The base is directed upwards, and, for the greater part of its extent, is directly continuous with the wall of the urinary bladder: the urethra enters it nearer its anterior than its posterior border.

The apex is directed downwards, and is in contact with the superior fascia of the urogenital diaphragm.

The posterior surface is flattened from side to side and slightly convex from above downwards; it is separated by its sheath and some loose connective tissue from the rectum, and is distant about 4 cm. from the anus. Near its upper border there is a depression through which the two ejaculatory ducts enter the prostate. This depression serves to divide the posterior surface into a lower larger and an upper smaller part. The upper smaller part constitutes the middle lobe of the prostate and intervenes between the ejaculatory ducts and the urethra; it varies greatly in size, and in some cases is destitute of glandular tissue. The lower larger portion sometimes presents a shallow median furrow, which imperfectly separates it into right and left lateral lobes; these form the main mass of the gland and are directly continuous with each other behind the urethra; they are connected in front of the urethra by a band which is named the isthmus: this consists of fibromuscular tissue and is devoid of glandular substance.

The anterior surface is narrow and convex from side to side. It lies about 2 cm. behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fatty tissue. It is connected to the pubic bones by the puboprostatic ligaments. The urethra emerges from this surface a little above and in front of the apex of the gland.

The lateral surfaces are prominent, and are covered by the anterior portions of the Levatores ani, which are, however, separated from the gland by a plexus of veins.

The prostate measures about 4 cm. transversely at the base, 2 cm. in its anteroposterior diameter, and 3 cm. in its vertical diameter. Its weight is about 8 gr. It is held in position by the puboprostatic ligaments; by the superior fascia of the urogenital diaphragm, which invests the prostate and the commencement of the membranous portion of the urethra; and by the anterior portions of the Levatores ani, which pass backwards from the os pubis and embrace the sides of the prostate. From the support they afford to the prostate these portions of the Levatores ani are named the *Levatores prostate*.

The prostate is perforated by the urethra and the ejaculatory ducts and contains the prostatic utricle. The urethra usually lies along the junction of its anterior with its middle third. The ducts pass obliquely downwards and forwards through the posterior part of the prostate, and open into the prostatic portion of the urethra (p. 1170).

Structure (fig. 1088).—The prostate is enveloped by a thin but firm capsule, distinct from that derived from the fascia endopelvina, and separated from it by a plexus of veins. This capsule is firmly adherent to the prostate and is structurally continuous with the stroma of the gland, being composed of the same tissues, viz. non-striped muscle and fibrous tissue. The substance of the prostate is of a pale reddish-grey colour, of great density, and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue constitutes the proper stroma of the prostate; the connective tissue being very scanty, and merely forming, between the muscular fibres, thin trabeculae in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: immediately beneath the capsule is a dense layer, which forms an investing sheath for the gland; around the prostatic part of the urethra is a dense layer of circular fibres, continuous above with the internal layer of the muscular coat of the

bladder, and blending below with the fibres surrounding the membranous portion of the urethra; between these two layers are strong bands of muscular tissue which decussate freely, and form meshes in which the glandular structure of the organ is imbedded. In that part of the gland which is situated in front of the urethra the muscular tissue is especially dense, and there is here little or no glandular tissue; while in that part which is behind the urethra the muscular tissue presents a wide-meshed structure, which is densest at the base of the gland—that is, near the bladder—becoming looser and more sponge-like towards the apex.

The *glandular substance* is composed of numerous follicles the lining of which frequently shows papillary elevations. The follicles open into elongated canals which join to form from twelve to twenty small excretory ducts. They are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma,

and enclosed in a delicate capillary plexus. The epithelium which lines the canal, and the terminal vesicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra, and are lined by two layers of epithelium, the inner layer consisting of columnar and the outer of small cubical cells. Small colloid masses, known as amyloid bodies, are often found in the gland tubes.

Vessels and Nerves.—The *arteries* supplying the prostate are derived from the internal pudendal, inferior vesical, and middle hæmorrhoidal arteries. Its *veins* form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and and in the hypogastric veins. The *nerves* are derived from the pelvic plexus.

Applied Anatomy.—By means of the finger introduced into the rectum, the surgeon detects enlargement or other disease of the prostate; he can feel the apex of the gland, which is the guide to Cock's operation for stricture; he is enabled also by the same means to direct the point of a catheter, when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel, the surgeon may, in some cases, especially in boys, learn the position, as well as the size, of a calculus in the bladder; and in the operation for its removal, if, as is not infrequently the case, it should be lodged behind an enlarged prostate, it may be displaced from its position by pressing it upwards towards the fundus of the bladder from the rectum. The prostate is occasionally the seat of suppuration, due to either gonorrhœa or tuberculous disease. The gland is enveloped in a dense unyielding capsule, which determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts

into the urethra, the direction in which there is least resistance, but may burst into the rectum, or more rarely in the perinæum. In advanced life the prostate sometimes becomes considerably enlarged and projects into the bladder so as to impede the passage of the urine. According to Messer's researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the condition affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the middle lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the internal urethral orifice, preventing the passage of the urine; and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate, a pouch is formed at the base of the bladder behind the projection, in which urine collects, and from which it cannot be entirely expelled. For this condition *prostatectomy* is sometimes done. The bladder is opened by an incision above the symphysis pubis, the mucous membrane of the post-prostatic pouch is scratched through, and the finger is then introduced into the space between the true capsule of the prostate and outer capsule formed by the fascia endopelvicina. Separation in this plane is then carried out below and laterally until the apex of the gland is reached. The whole of the work is done with the finger, which is gradually swept round the sides until the anterior surface is reached and freed. The gland is then, by traction, displaced into the bladder and removed, usually carrying with it the greater portion of the mucous membrane of the prostatic urethra. Hæmorrhage, which may be considerable at times, is checked by hot irrigations, and the bladder is temporarily drained. Very satisfactory results have followed this operation.

The prostate can be reached from the perinæum, and in some cases the enlarged gland has been removed by this route, but the perineal approach is not usually employed except in the case of abscess of or about the gland.

THE BULBO-URETHRAL GLANDS

The **bulbo-urethral glands** (Cowper's glands) are two small, rounded and somewhat lobulated bodies, of a yellow colour, each about the size of a pea, placed laterally to the membranous portion of the urethra, between the two layers of the fascia of the urogenital diaphragm. They lie close above the urethral bulb, and are enclosed by the transverse fibres of the *Sphincter urethræ membranacæ*. They gradually diminish in size as age advances.

The excretory duct of each gland, nearly 3 cm. long, passes obliquely forwards beneath the mucous membrane, and opens by a minute orifice on the floor of the cavernous portion of the urethra about 2.5 cm. in front of the urogenital diaphragm.

Structure.—Each gland is made up of several lobules which are held together by a fibrous investment. Each lobule consists of a number of acini, lined by columnar epithelial cells.

THE FEMALE GENITAL ORGANS

The female genital organs consist of an internal and an external group. The *internal organs* are situated within the pelvis, and consist of the ovaries, the uterine tubes, the uterus, and the vagina. The *external organs* are placed below and in front of the pubic arch. They comprise the mons pubis, the labia majora et minora pudendi, the clitoris, the bulbus vestibuli, and the greater vestibular glands.

THE OVARIES

The **ovaries**, two in number, are homologous with the testes in the male. They are situated one on either side of the uterus in relation to the lateral wall of the pelvis, and attached to the back of the broad ligament of the uterus behind and below the uterine tube (fig. 1089). They are of a greyish-pink colour, and present either a smooth or a puckered uneven surface; each is about 3 cm. long, 1.5 cm. wide, and about 10 mm. thick. In the erect posture the long axis of the ovary is vertical. Each ovary presents a lateral and a medial surface, a tubal and a uterine extremity, and a mesovarian and a free border. The ovary lies in a depression, named the *ovarian fossa*, on the lateral

wall of the pelvis; this fossa is bounded in front by the obliterated hypogastric artery, and behind by the ureter and the uterine artery. The exact position of the ovary has been the subject of considerable difference of opinion, and the description here given applies to the ovary of the nulliparous woman; the

FIG. 1089.—The uterus and the right broad ligament, seen from behind. The broad ligament has been spread out and the ovary drawn downwards.

ovary is displaced during the first pregnancy, and probably never again returns to its original position. The *tubal extremity* (*extremitas tubaria*) is near the external iliac vein; to it are attached the ovarian fimbria of the uterine tube and a fold of peritoneum, the *suspensory ligament of the ovary*, which passes upwards over the iliac vessels and contains the ovarian vessels and nerves.

FIG. 1090.—The adult ovary, epoöphoron, and uterine tube.
(From Farre, after Kobelt.)

a, a. Epoöphoron formed from the upper part of the Wolffian body. b. Remains of the uppermost tubes sometimes forming hydatids. c. Middle set of tubes. d. Some lower atrophied tubes. e. Atrophied remains of the Wolffian duct. f. The terminal bulb or hydatid. h. The uterine tube. i. Hydatid attached to the extremity. l. The ovary.

The *uterine extremity* (*extremitas uterina*) is directed downwards towards the pelvic floor; it is usually narrower than the tubal, and is attached to the lateral angle of the uterus, immediately behind the uterine tube, by a rounded cord termed the *ligament of the ovary*, which lies within the broad ligament

and contains some non-striped muscular fibres. The *lateral surface* is in contact with the parietal peritoneum, which lines the ovarian fossa and separates the ovary from the subperitoneal connective tissue and the obturator vessels; the *medial surface* is to a large extent covered by the uterine tube. The *mesovarian border* is straight and is directed towards the obliterated hypogastric artery; it is attached to the back of the broad ligament by a short fold named the *mesovarium*. Between the two layers of this fold the blood-vessels and nerves

pass to the hilum of the ovary.

The *free border* is convex, and is directed towards the ureter. The uterine tube arches over the ovary, running upwards in relation to its mesovarian border, curving over its tubal extremity, and then passing downwards on its free border and medial surface.

In the foetus, the ovaries are situated, like the testes, in the lumbar region near the kidneys, but they gradually descend into the pelvis (p. 152):

marked by a line around the anterior border of the ovary. The ovary consists of a number of vesicular ovarian follicles imbedded in the meshes of a stroma or framework.

The *stroma* is abundantly supplied with blood-vessels, and consists for the most part of spindle-shaped cells with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriped muscle-cells, by others as connective tissue cells. On the surface of the organ this tissue is much condensed, and forms a layer known as the *tunica albuginea*. The stroma of the ovary also contains groups of *interstitial cells* resembling those of the testis.

Vesicular ovarian (Graafian) follicles.

Upon making a section of an ovary, numerous vesicles of various sizes are to be seen; they are the follicles, or ovisacs containing the ova. Immediately beneath the tunica albuginea is a layer of stroma, called the *cortical layer*, characterised by the presence of a large number of ova in an early stage of development. At this stage each ovum is a spherical cell, and is surrounded by a single layer of smaller, cubical cells, the whole being about 0.25 mm. in diameter. These primitive follicles are numerous in the ovary of the child. After puberty some of them become enlarged and pass towards the interior of the ovary: the investing cells multiply, and later a cavity appears in the mass of cells thus formed.

The fully developed follicle (fig. 1092) is about 1.5 cm. in diameter, and consists of an external fibrovascular coat, connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, which consists of several layers of nucleated cells, called the *membrana granulosa*. At one part of the mature follicle the cells of the *membrana granulosa* are collected into a mass which projects into the cavity

Structure (fig. 1091).—The surface of the ovary is covered by a layer of columnar cells. This epithelium gives to the ovary a dull grey colour as compared with the shining smoothness of the peritoneum; the transition between the squamous epithelium of the peritoneum and the columnar cells which cover the ovary is usually

FIG. 1092.—A section through an ovarian follicle of a cat. $\times 50$.

of the follicle. This is termed the *discus proligerus*, and in it the ovum is imbedded.* The follicle contains a transparent albuminous fluid, the *liquor folliculi*. As the follicle approaches maturity it again comes to the surface of the ovary, where it appears as a thin-walled vesicle. From the time of puberty to the end of the fruitful period of woman's life, the ovary shows a number of these vesicles. Periodically a vesicle ruptures and the ovum is set free together with the greater part of the *discus proligerus*, and is conveyed by the uterine tube to the cavity of the uterus.

The development and maturation of the follicles and ova continue uninterruptedly from puberty to the end of the reproductive period of woman's life, while their formation commences before birth.

Discharge of an ovum.—A follicle, after attaining a certain stage of development, gradually approaches the surface of the ovary and bursts; the ovum and fluid contents of the follicle are liberated on the exterior of the ovary, and carried into the uterine tube by currents set up by the movements of the cilia covering the mucous membrane of the fimbriae.

Corpus luteum.—After the discharge of the ovum a series of changes occurs within the Graafian follicle which result in the formation of a structure named the *corpus luteum*. When fully developed this consists of large cells containing yellow pigment (*luteal cells*) separated from one another by delicate trabeculae of highly vascular connective tissue which is aggregated to form a mass in the centre of the follicle devoid of cells. The luteal cells are probably derived from the epithelial cells of the Graafian follicle. These cells undergo great hypertrophy, and, in the early stages of the formation of the corpus luteum, show signs of mitosis. The connective tissue trabeculae are derived from the sheath of the follicle.

If the discharged ovum be not fertilized the corpus luteum quickly degenerates, and within two months is reduced to a small cicatrix, but if the ovum be fertilized the corpus luteum increases in size and, by the middle of pregnancy, may measure about 2.5 cm. in diameter. During the later months of pregnancy the luteal cells lose their colour, and the size of the corpus luteum diminishes, so that by the end of pregnancy its diameter is reduced to about 1 cm.†

Vessels and Nerves.—The arteries of the ovaries and uterine tubes are the ovarian from the aorta. Each anastomoses freely in the mesosalpinx with the uterine artery; it gives some branches to the uterine tube, and others which traverse the mesovarium and enter the hilum of the ovary. The veins emerge from the hilum in the form of a plexus, the *pampiniform plexus*; the ovarian vein is formed from this plexus, and leaves the pelvis in company with the artery. The nerves are derived from the hypogastric or pelvic plexus, and from the ovarian plexus, the uterine tube receiving a branch from one of the uterine nerves.

Epoöphoron (figs. 1089, 1090).—The epoöphoron or organ of Rosenmüller lies in the lateral part of the mesosalpinx between the ovary and the uterine tube, and consists of a few short tubules (*ductuli transversi*) which converge towards the ovary while their opposite ends open into a rudimentary duct, the *ductus longitudinalis epoöphori* (duct of Gärtner), which runs in the broad ligament of the uterus, parallel with the lateral part of the uterine tube.

In a small proportion of cases Gärtner's duct can be followed alongside the uterus to near the level of the internal orifice. Here it pierces the muscular wall of the uterus and descends in the cervix uteri, gradually approaching the mucous membrane, without however quite reaching it. The duct then runs downwards in the lateral wall of the vagina and ends at, or close to, the free margin of the hymen.

Paroöphoron.—The paroöphoron consists of a few scattered rudimentary tubules, best seen in the child, situated in the broad ligament between the epoöphoron and the uterus.

The ductuli transversi of the epoöphoron and the tubules of the paroöphoron are remnants of the tubules of the Wolffian body or mesonephros: the ductus longitudinalis epoöphori is a persistent portion of the Wolffian duct.

Applied Anatomy.—The inflammations which affect the ovary are merely an extension of those from the uterine tube. Ovarian new formations are of common occurrence, and are either solid or cystic; the former being the less common. The 'ovarian cysts' in the majority of cases are cystadenomata which may spring from the ovarian follicles and assume enormous dimensions; in rarer instances they arise from the tubules at the hilum of the ovary or those of the epoöphoron; in other instances a clear watery cyst forms between the layers of the broad ligament. An ovarian cyst, once diagnosed, should always be removed, as it is liable to become affected by suppuration, torsion of its pedicle, or other serious complications. The operation for its removal, badly termed *ovariotomy*, consists in opening the abdomen and delivering the cyst through the wound; the pedicle is then clamped with forceps, and the cyst is cut free. The pedicle must be transfixed and securely ligatured by an interlocking ligature, which will not slip off. The pedicle consists of an elongated part of the broad ligament, including the uterine tube and ovarian artery, and a great number of large veins. Ovariectomy for a simple uncomplicated cyst presents no special difficulties, but, in cases where there are old adhesions implicating the small intestine, it may present very great difficulties.

* The ovum is described on pp. 41 to 43.

† Consult *The Physiology of Reproduction* by F. H. A. Marshall, 1910.

THE UTERINE TUBES (figs. 1089, 1094)

The **uterine tubes** (Fallopian tubes), two in number, transmit the ova from the ovaries to the cavity of the uterus and are situated in the upper margins of the broad ligaments of the uterus. Each tube is about 10 cm. long, and one end of it opens into the superior angle of the cavity of the uterus, the other into the peritoneal cavity close to the ovary. The opening into the uterine cavity is very small, and only admits a fine bristle. The opening into the peritoneal cavity is named the *abdominal ostium*, and when its muscular wall is relaxed has a diameter of about 3 mm. The abdominal ostium is situated at the bottom of a trumpet-shaped expansion of the uterine tube, termed the *infundibulum*, the circumference of which is prolonged into a varying

FIG. 1093.—Transverse section of human uterine tube stained with hæmatoxylin and eosin. $\times 14$.

number of irregular processes, called *fimbriae*, and therefore this ostium is sometimes called the *fimbriated end* of the tube. The inner surfaces of the fimbriae are lined by mucous membrane, and in the larger fimbriae this exhibits longitudinal folds which are continuous with similar folds in the mucous lining of the infundibulum. One fimbria, longer and more deeply grooved than the others, is attached to the tubal extremity of the ovary, and is named the *ovarian fimbria*. The infundibulum opens into the *ampulla* of the tube, which is thin-walled and tortuous and forms rather more than half the entire length of the tube. The ampulla is succeeded by the *isthmus*, which is round and cord-like and constitutes approximately the medial third of the tube. The part continued from the isthmus through the wall of the uterus is about 1 cm. long, and is named the *pars uterina tube*.

The uterine tube is directed lateralwards as far as the uterine extremity of the ovary, and then ascends along the mesovarian border of the ovary to the tubal extremity, over which it arches; finally it turns downwards and ends in relation to the free border and medial surface of the ovary. In connexion with the fimbriae of the uterine tube, or with the broad ligament close to them, there are frequently one or more small pedunculated vesicles; these are termed the *appendices vesiculosae* (hydatids of Morgagni).

Structure (fig. 1093).—The uterine tube consists of three coats: serous, muscular, and mucous. The *external* or *serous coat* is peritoneal. The *middle* or *muscular coat* consists

of an external longitudinal and an internal circular layer of non-striped muscular fibres continuous with those of the uterus. The *internal* or *mucous coat* is continuous with the mucous lining of the uterus, and, at the abdominal ostium of the tube, with the peritoneum. It is thrown into longitudinal folds, which in the ampulla are much more extensive than in the isthmus. The lining epithelium is columnar and ciliated. This form of epithelium is also found on the inner surfaces of the fimbriae; while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

Applied Anatomy.—The majority of the diseases of the uterine tube are due to infections which have spread by way of the vagina and uterus, and the disease often does not stop at the uterine tube, but passes on to the peritoneum, giving rise to acute general peritonitis, or a localised condition termed *perimetritis* that may be acute or chronic. Perimetritis is often followed by various painful conditions, which are due to the peritoneal adhesions resulting from the inflammation of the serous membrane, and which persist throughout life. Tubal inflammation (*salpingitis*) is usually the result of an infection either by the gonococcus, or by septic organisms implanted at the time of labour or abortion. In many cases the fimbriated ends of the tubes become closed by adhesions, pus collects in the tubes, and a *pyosalpinx* results.

Fertilisation of the ovum (p. 47) is believed to occur in the uterine tube, and the fertilised ovum is then normally passed on into the uterus; the ovum, however, may adhere to and undergo development in the tube, giving rise to the commonest variety of *ectopic gestation*. In such cases the amnion and chorion are formed, but a true decidua is never present; and the gestation usually ends by extrusion of the ovum through the abdominal ostium, although it is not uncommon for the tube to rupture into the peritoneal cavity, this being accompanied by severe hæmorrhage, and needing surgical interference.

THE UTERUS (figs. 1089, 1094, 1095)

The *uterus*, or *womb*, is a hollow, thick-walled, muscular organ situated in the pelvic cavity between the urinary bladder and the rectum. Into its upper part the uterine tubes open, one on either side, while below, its cavity

FIG. 1094:—The female pelvis and its contents, seen from above and in front.

communicates with that of the vagina. When the ova are discharged from the ovaries they are carried to the uterine cavity through the uterine tubes. If an ovum be fertilised it imbeds itself in the uterine wall and is normally retained in the uterus until prenatal development is completed, the uterus undergoing changes in size and structure to accommodate itself to the needs

of the growing embryo. After parturition the uterus returns almost to its former condition, but certain traces of its enlargement remain. For general descriptive purposes the adult virgin uterus is taken as the type form.

In the virgin state the uterus is flattened from before backwards and is pyriform in shape, with the apex directed downwards and backwards. It lies between the bladder below and in front and the sigmoid colon and rectum above and behind, and is completely within the pelvis, its base being below the level of the superior pelvic aperture. Its upper part is suspended by the broad and the round ligaments, while its lower portion is imbedded in the fibrous tissue of the pelvis.

The long axis of the uterus usually lies approximately in the axis of the superior pelvic aperture, but as the organ is freely movable its position varies

FIG. 1095. --A median sagittal section of the female pelvis.

with the state of distension of the bladder and rectum. Except when much displaced by a distended bladder, it forms a forward angle with the vagina, since the axis of the vagina corresponds to the axes of the cavity and inferior aperture of the pelvis.

The uterus measures about 7.5 cm. in length, 5 cm. in breadth at its upper part, and nearly 2.5 cm. in thickness; it weighs from 30 to 40 gm. It is divisible into two portions. On the surface, a little below the middle, is a slight constriction, known as the *isthmus*, and corresponding to this in the interior is a narrowing of the uterine cavity, the *internal orifice* of the uterus. The portion above the isthmus is termed the *body*, and that below, the *cervix*. The part of the body which lies above a plane passing through the points of entrance of the uterine tubes is known as the *fundus*.

Body.—The body gradually narrows from the fundus to the isthmus.

The *vesical* or *anterior surface* is in apposition with the urinary bladder. It is flattened and covered by peritoneum, which is reflected on to the bladder to form the vesico-uterine excavation.

The *intestinal* or *posterior surface* is convex transversely, and is covered by peritoneum, which is continued downwards on to the cervix uteri and the upper part of the vagina. It is in relation with the sigmoid colon, from which it is usually separated by some coils of small intestine.

The *fundus* is convex in all directions, and covered by peritoneum continuous with that on the vesical and intestinal surfaces. On it rest some coils of small intestine, and occasionally the distended sigmoid colon.

The *lateral margins* are slightly convex. At the upper end of each the uterine tube pierces the uterine wall. Below and in front of this point the round ligament of the uterus is fixed, while below and behind it is the attachment of the ligament of the ovary. These three structures lie within a fold of peritoneum which is reflected from the margin of the uterus to the wall of the pelvis, and is named the broad ligament.

Cervix.—The cervix is the lower constricted segment of the uterus. It is somewhat conical in shape, with its truncated apex directed downwards and backwards, but is slightly wider in the middle than above or below. Owing to its relationships it is less freely movable than the body, so that its long axis is seldom in the same straight line as that of the body. The long axis of the uterus as a whole presents the form of a curved line with its concavity forwards, or in extreme cases may present an angular bend at the region of the isthmus uteri.

The cervix projects through the anterior wall of the vagina, which divides it into an upper, supravaginal portion, and a lower, vaginal portion.

The *supravaginal portion* is separated in front from the bladder by cellular tissue (*parametrium*), which extends also on to the sides of the cervix, and lateralwards between the layers of the broad ligaments. The uterine arteries reach the margins of the cervix in this fibrous tissue, while on either side the *ureter* runs downwards and forwards in it at a distance of about 2 cm. from the cervix. *Posteriorly*, the supravaginal cervix is covered by peritoneum, which is prolonged below on to the posterior vaginal wall, whence it is reflected on to the rectum, forming the recto-uterine excavation. It is in relation with the rectum, from which it may be separated by coils of small intestine.

The *vaginal portion* of the cervix projects into the anterior wall of the vagina between the vaginal fornices. On its projecting rounded extremity is a small, depressed, somewhat circular aperture, the *external orifice* of the uterus, through which the cavity of the cervix communicates with that of the vagina. The external orifice is bounded by two lips, an anterior and a posterior, of which the anterior is the shorter and thicker, although, on account of the slope of the cervix, it projects lower than the posterior. Normally both lips are in contact with the posterior vaginal wall.

Interior of the uterus (fig. 1096).—The cavity of the uterus is small in comparison with the size of the organ.

The *cavity of the body* is a mere slit, flattened from before backwards. It is triangular in shape, the base being formed by the internal surface of the fundus between the orifices of the uterine tubes, the apex by the internal orifice of the uterus; through this orifice the cavity of the body communicates with the canal of the cervix.

The *canal of the cervix* is somewhat fusiform, flattened from before backwards, and broader at the middle than at either end. It communicates above, through the internal orifice, with the cavity of the body, and below, through the external orifice, with the vaginal cavity. The wall of the canal presents an anterior and a posterior longitudinal ridge, from each of which proceed a number of small oblique columns, the *palmate folds*, giving the

FIG. 1096.—The posterior half of the uterus and upper part of the vagina.

appearance of branches from the stem of a tree; to this arrangement the name *arbor vitae uterina* is applied. The folds on the two walls are not opposed, but fit between one another so as to close the cervical canal.

The total length of the uterine cavity from the external orifice to the fundus is about 6 cm.

Ligaments.—The ligaments of the uterus are eight in number; an anterior; a posterior; two lateral or broad; two uterosacral; and two round ligaments.

The *anterior ligament* consists of the vesico-uterine fold of peritoneum, which is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body.

The *posterior ligament* consists of the rectovaginal fold of peritoneum, which is reflected from the back of the posterior fornix of the vagina on to the front of the rectum. It forms the bottom of a deep pouch called the *recto-uterine excavation* (pouch of Douglas), which is bounded in front by the

FIG. 1097.—A sagittal section through the pelvis of a new-born female child. Some coils of the small intestine which intervened between the uterus and the bladder have been removed.

posterior wall of the uterus, the supravaginal cervix, and the posterior fornix of the vagina; behind, by the rectum; and laterally by two crescentic folds of peritoneum which pass backwards from the cervix uteri on either side of the rectum to the posterior wall of the pelvis. These folds are named the *sacro-genital*, or *recto-uterine*, folds. They contain a considerable amount of fibrous tissue and non-striped muscular fibres which are attached to the front of the sacrum and constitute the *uterosacral ligaments*.

The *two lateral or broad ligaments* pass from the sides of the uterus to the lateral walls of the pelvis. Together with the uterus they form a septum across the female pelvis, dividing that cavity into two portions. The anterior part contains the bladder; the posterior part, the rectum, and in certain conditions some coils of the small intestine. Between the two layers of each broad ligament are: (1) the uterine tube; (2) the round ligament of the uterus; (3) the ovary and its ligament; (4) the epoöphoron and paroöphoron; (5) connective tissue; (6) unstriped muscular fibres; and (7) blood-vessels and nerves. The portion of the broad ligament which stretches from the uterine tube to the level of the ovary is named the *mesosalpinx*. Between the fimbriated extremity of the uterine tube and the lower attachment of the broad ligament is a concave rounded margin, called the *infundibulopelvic ligament*.

The *round ligaments* are two flattened bands between 10 cm. and 12 cm. in length, situated between the layers of the broad ligament in front of and below the uterine tubes. Commencing on either side at the lateral angle of

the uterus, each ligament is directed forwards, upwards, and lateralwards over the external iliac vessels. It then passes through the abdominal inguinal ring and along the inguinal canal to the labium majus, in which it is lost. The round ligaments consist principally of muscular tissue prolonged from the uterus; also of some fibrous and areolar tissue, besides blood-vessels, lymphatics, and nerves, enclosed in a duplicature of peritoneum, which, in the foetus, is prolonged in the form of a tubular process (canal of Nuck) for a short distance into the inguinal canal. The canal of Nuck is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the saccus vaginalis which precedes the descent of the testis.

In addition to the ligaments just described, there is a band named the *ligamentum transversale colli* (Mackenrodt) on either side of the cervix uteri. It is attached to the side of the cervix uteri and to the vault and lateral fornix of the vagina, and is continuous externally with the fibrous tissue which surrounds the pelvic blood-vessels.

FIG. 1098.-A vertical section through the mucous membrane of a human uterus.
(Sobotta.)

The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

In the *foetus* the uterus is contained in the abdominal cavity, projecting beyond the superior aperture of the pelvis (fig. 1097). The cervix is considerably larger than the body.

At *puberty* the uterus is pyriform in shape, and weighs from 14 to 17 grs. The fundus is just below the level of the superior aperture of the pelvis. The palmate folds are distinct, and extend to the upper part of the cavity.

The position of the uterus in the *adult* is liable to considerable variation, depending chiefly on the condition of the bladder and rectum. When the bladder is empty the entire uterus is directed forwards, and is at the same time bent on itself at the junction of the body and cervix, so that the body lies upon the bladder. As the latter fills, the uterus gradually becomes more and more erect, until with a fully distended bladder the fundus may be directed backwards towards the sacrum.

During *menstruation* the organ is enlarged, and more vascular, and its surfaces are rounder; the external orifice is rounded, its labia swollen, and the lining membrane of the body is thicker, softer, and of a darker colour.

During *pregnancy* the uterus becomes enormously enlarged, and in the eighth month reaches the epigastric region. The increase in size is partly due to growth of pre-existing muscle, and partly to development of new fibres.

After *parturition* the uterus nearly regains its usual size, weighing about 42 gr.; but its cavity is larger than in the virgin state, its vessels are tortuous, and its muscular

layers are more defined; the external orifice is more marked, and its edges present one or more fissures.

In old age the uterus becomes atrophied, and paler, and denser in texture; a more distinct constriction separates the body and cervix. The internal orifice is frequently, and the external orifice occasionally, obliterated, while the lips almost entirely disappear.

Structure.—The uterus is composed of three coats: an external or serous, a middle or muscular, and an internal or mucous.

The *serous coat* is derived from the peritoneum; it invests the fundus and the whole of the intestinal surface of the uterus; but covers the vesical surface only as far as the junction of the body and cervix. In the lower fourth of the intestinal surface the peritoneum is not closely connected with the uterus, being separated from it by a layer of loose cellular tissue and some large veins.

The *muscular coat* forms the chief bulk of the substance of the uterus. In the virgin it is dense, firm, of a greyish colour, and cuts almost like cartilage. It is thick opposite

FIG. 1099.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

the middle of the body and fundus, and thin at the orifices of the uterine tubes. It consists of bundles of unstripped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. The layers are three in number: external, middle and internal. The external and middle layers constitute the muscular coat proper, while the internal layer is a greatly hypertrophied *muscularis mucosæ*. During pregnancy the muscular tissue becomes more prominently developed, the fibres being greatly enlarged.

The external layer, placed beneath the peritoneum, is disposed as a thin plane on the vesical and intestinal surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each lateral angle of the uterus, are continued on to the uterine tube, the round ligament, and the ligament of the ovary: some passing at each side into the broad ligament, and others running backwards from the cervix into the sacro-uterine ligaments. The middle layer of fibres presents no regularity in its arrangement, being disposed longitudinally, obliquely, and transversely. It contains many blood-vessels. The internal layer consists of circular fibres arranged in the form of two hollow cones, the apices of which surround the orifices of the uterine tubes, their bases intermingling with one another on the middle of the body of the uterus. At the internal orifice these circular fibres form a distinct sphincter. The internal muscular layer is separated from the muscular coat proper by a number of large blood-vessels lying in what represents a submucous coat.

The *mucous membrane* (fig. 1098) is smooth, and closely adherent to the subjacent tissue. It is continuous, through the fimbriated extremities of the uterine tubes, with the peritoneum; and, through the external uterine orifice, with the lining of the vagina.

In the body of the uterus the mucous membrane is smooth, soft, of a pale red colour, lined by columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles, arranged perpendicularly to the surface. The structure of the corium differs from that of ordinary mucous membranes, and consists of an embryonic nucleated and highly cellular form of connective tissue in which run numerous large lymphatics. In it are the tube-like uterine glands, lined by ciliated columnar epithelium. They are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged and elongated, presenting a contorted or wavy appearance.

In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphe. In the upper two-thirds of the canal, the mucous membrane is provided with numerous deep glandular follicles which secrete a clear viscid alkaline mucus; and, in addition, extending through the whole length of the canal is a variable number of little cysts, presumably follicles which have become occluded and distended with retained secretion. They are called the *agula Nabothi*. The mucous membrane covering the lower half of the cervical canal presents numerous papillae. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and, close to the external orifice, changes to stratified squamous epithelium. On the vaginal surface of the cervix the epithelium is similar to that lining the vagina, viz. stratified squamous.

Vessels and Nerves.—The arteries of the uterus are the uterine, from the hypogastric; and the ovarian, from the abdominal aorta (fig. 1099). They are remarkable for their tortuous course in the substance of the organ, and for their frequent anastomoses. The termination of the ovarian artery meets that of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus, their disposition being circular. The veins are of large size, and correspond with the arteries. They end in the uterine plexuses. In the impregnated uterus the arteries carry the blood to, and the veins convey it away from, the intervillous space of the placenta (p. 62). The lymphatics are described on p. 735. The nerves are derived from the hypogastric and ovarian plexuses, and from the third and fourth sacral nerves.

Applied Anatomy.—A certain amount of anteversion or retroversion of the uterus can take place without the conditions being regarded as pathological, but when the degree of flexion at the junction of the body with the cervix becomes considerable it must be regarded as a morbid condition. This is especially true of retroversion combined with retroflexion. Retroversion alone is a falling back of the whole uterus, so that the cervix points upwards towards the os pubis; retroflexion is a bending backwards of the body, the cervix remaining in its normal position. The two conditions are usually combined. Prolapse of the uterus is another common infirmity. The organ sinks to an abnormally low level in the pelvis, and sometimes protrudes beyond the vulva. This is due to the supporting mechanism of the uterus being insufficient to sustain the strain thrown upon it.

The uterus may require removal in cases of malignant disease or for fibroid tumours. Carcinoma is the most common form of malignant disease of the uterus. It may show itself either as a columnar carcinoma or as a squamous carcinoma; the former commencing either in the cervix or body of the uterus; the latter always commencing in the epithelial cells of the mucous covering of the vaginal surface of the cervix. Cancer of the body or of the cervix may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section, but if the body be much enlarged the former operation is impossible. Vaginal hysterectomy is now rarely performed.

In the treatment of uterine fibroids which require operative interference, removal of the whole body of the uterus, together with the tumours, with or without the cervix, through an abdominal incision, gives the most satisfactory results. After the abdomen has been opened the ovarian vessels are secured (one ovary at least being left, provided it be healthy) and the broad ligaments are divided. It will now be found that the uterus can be raised out of the pelvis, and a transverse incision is made through the peritoneum, where it is reflected from the front of the uterus on to the back of the bladder, and this viscus is separated from the surface of the uterus. The uterus is now turned forwards and the peritoneum of the recto-uterine excavation incised transversely. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A ligature is made to encircle this as close to the uterus as possible, the position of the ureter being always kept in mind, and, after having been tied, the structures are divided between the ligature and the uterus. The body of the uterus can now be removed by cutting it across at its junction with the cervix, or if desired the vaginal wall can be incised both front and back and the cervix removed together with the body. The peritoneum is finally sewn up carefully across the floor of the pelvis, with a transverse line of suture from one uterine tube to the other, so as to leave no raw surface to which small intestine can adhere.

Inflammation of the cellular tissue surrounding the cervix occasionally takes place. Laceration of the cervix by instruments or by the foetal head frequently occurs, opening up the cellular planes and so exposing them to any infection that may be present. An inflammatory mass forms in the cellular tissue between the layers of the broad ligament

or of the uterosacral ligaments, and the condition is termed *pelvic cellulitis*, or *parametritis*. This condition is usually confined to one side of the pelvis, forming a large inflammatory mass which pushes the uterus over to the opposite side. It does not always remain localised, however, but may spread widely, surrounding the rectum or the neck of the bladder, or mounting into the iliac fossa, or even to the perinephric cellular tissue. The condition may resolve or an abscess may form. In the former condition the cicatrization of the inflammatory products produces displacements of the uterus towards the affected side of the pelvis, or may result in stricture of the rectum when that viscus has been surrounded by the process. When suppuration ensues, the pus may burst into the bladder, vagina, or rectum, or it may present above the inguinal ligament, or it may mount to the anterior abdominal wall in front of the bladder or to the posterior abdominal wall between the iliac crest and last rib. The abscess may, moreover, make its way into the buttock by passing out of the pelvis through the greater sciatic foramen, or it may pass down between the fibres of the Levator ani and appear as a secondary ischiorectal abscess.

THE VAGINA (fig. 1095)

The **vagina** extends from the vestibule to the uterus, and is situated behind the bladder and in front of the rectum; it is directed upwards and backwards, its axis forming with that of the uterus an angle of over ninety degrees, opening forwards. Its walls are ordinarily in contact, and the usual shape of its lower part on transverse section is that of an H, the transverse limb being slightly curved forwards or backwards, while the lateral limbs are somewhat convex towards the median line; its middle part has the appearance of a transverse slit. Its length is 6 cm. to 7.5 cm. along its anterior wall, and 9 cm. along its posterior wall. It is constricted at its commencement, dilated in the middle, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the external orifice of the uterus, its attachment extending higher up on the posterior than on the anterior wall of the uterus. To the recess behind the cervix the term *posterior fornix* is applied, while the smaller recesses in front and at the sides are called the *anterior* and *lateral fornices*.

The *anterior wall* of the vagina is in relation with the fundus of the bladder, and with the urethra. Its *posterior wall* is separated from the rectum by the recto-uterine excavation in its upper fourth, and by the rectovesical fascia in its middle two-fourths; the lower fourth is separated from the anal canal by the perineal body. Its sides are enclosed between the Levatores ani muscles. As the terminal portions of the ureters pass forwards and medialwards to reach the fundus of the bladder, they run close to the lateral fornices of the vagina, and as they enter the bladder are slightly in front of the anterior fornix.

Structure.—The vagina consists of an internal mucous lining and a muscular coat, separated by a layer of erectile tissue.

The *mucous membrane* is continuous above with that lining the uterus. Its inner surface presents two longitudinal ridges, one on its anterior and the other on its posterior wall. These ridges are called the *columns of the vagina*, and from them numerous transverse ridges or rugæ extend outwards on either side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ; they are most numerous near the orifice of the vagina, especially before parturition. The epithelium of the mucous membrane is of the stratified squamous variety. The mucous coat contains a number of mucous crypts, but no true glands.

The *muscular coat* consists of two layers: an external longitudinal, which is by far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the rectovesical fascia on either side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi, which pass from the one layer to the other. In addition to this, the lower end of the vagina is surrounded by a band of striped muscular fibres, the *Sphincter vaginae* (p. 476).

External to the muscular coat is a layer of connective tissue, containing a large plexus of blood-vessels.

The *erectile tissue* is situated between the mucous membrane and the muscular coat; it consists of a layer of loose connective tissue, imbedded in which is a plexus of large veins, and numerous bundles of unstriped muscular fibres, derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

EXTERNAL ORGANS (fig. 1100)

The external genital organs of the female are: the mons pubis, the labia majora et minora pudendi, the clitoris, the vestibule of the vagina, the bulb of the vestibule, and the greater vestibular glands. The term *pudendum* or *vulva*, as generally applied, includes all these parts.

The mons pubis (mons Veneris), the rounded eminence in front of the pubic symphysis, is formed by a collection of fatty tissue beneath the skin. It becomes covered with hair at the time of puberty.

FIG. 1100.—The external genital organs of the female. The labia have been drawn apart.

The labia majora are two prominent longitudinal cutaneous folds which extend downwards and backwards from the mons pubis, and form the lateral boundaries of a fissure or cleft, the *pudendal cleft* or *rima*, into which the vagina and urethra open. Each labium has two surfaces, an outer, pigmented and covered with crisp hairs; and an inner, smooth and beset with large sebaceous follicles. Between the two surfaces there is a considerable quantity of areolar tissue, fat, and a tissue resembling the dartos tunic of the scrotum, besides vessels, nerves, and glands. The labia are thicker in front, where they form by their meeting the *anterior labial commissure*. Posteriorly they are not really joined, but appear to become lost in the neighbouring integument, ending close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the *posterior labial commissure*, or posterior boundary of the pudendum. The interval between the posterior commissure and the anus, from 2.5 cm. to 3 cm. in length, constitutes the *gynaecological perinaeum*.

The labia minora are two small cutaneous folds, situated between the labia majora, and extending from the clitoris obliquely downwards, lateralwards, and backwards for about 4 cm. on either side of the orifice of the vagina,

between which and the labia majora they end; in the virgin the posterior ends of the labia minora are usually joined across the middle line by a fold of skin, named the *frenulum of the labia*, or *fourchette*. Anteriorly, each labium minus divides into two portions: the upper division passes above the clitoris to meet its fellow of the opposite side, forming a fold which overhangs the glans clitoridis, and is named the *præputium clitoridis*; the lower division passes beneath the clitoris and is united to its under surface, forming, with its fellow of the opposite side, the *frenulum of the clitoris*. On the opposed surfaces of the labia minora are numerous sebaceous follicles.

The vestibule.—The cleft between the labia minora is named the *vestibule of the vagina*: in it are the urethral and vaginal orifices and the openings of the ducts of the greater vestibular glands. The part of the vestibule between the vaginal orifice and the frenulum of the labia consists of a shallow depression named the *navicular fossa*.

The clitoris is an erectile structure, homologous with the penis. It is situated beneath the anterior labial commissure, partially hidden between the anterior ends of the labia minora. It consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their medial surfaces by an incomplete fibrous pectiniform septum; each corpus cavernosum is connected to the pubic and ischial rami by a crus. The free extremity, or *glans clitoridis*, is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. The clitoris is provided, like the penis, with a suspensory ligament, and with two small muscles, the Ischio-cavernosi, which are inserted into the crura of the clitoris.

The external urethral orifice is placed about 2.5 cm. behind the glans clitoridis and immediately in front of the orifice of the vagina: it usually assumes the form of a short, sagittal cleft with slightly raised margins.

The vaginal orifice is a median slit below and behind the opening of the urethra; its size varies inversely with that of the hymen.

The hymen is a thin fold of mucous membrane situated at the orifice of the vagina; the inner surfaces of the fold are normally in contact with each other, and the vaginal orifice appears as a cleft between them. The hymen varies much in shape. When stretched, its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar fold, with its concave margin turned towards the pubes. Occasionally it is cribriform, or its free margin forms a membranous fringe. It may be entirely absent, or may form a complete septum across the lower end of the vagina; the latter condition is known as an imperforate hymen. When the hymen has been ruptured, small rounded elevations known as the *caruncule hymenales* are found as its remains.

The bulb of the vestibule is the homologue of the urethral bulb and adjoining part of the corpus cavernosum urethræ of the male, and consists of two elongated masses of erectile tissue, placed one on either side of the vaginal orifice and united to each other in front by a narrow median band termed the *pars intermedia*. Each lateral mass measures about 3 cm. in length. Their posterior ends are expanded and are in contact with the greater vestibular glands; their anterior ends are tapered and joined to one another by the pars intermedia; their deep surfaces are in contact with the inferior fascia of the urogenital diaphragm; superficially they are covered by the Bulbocavernosus.

The greater vestibular glands (glands of Bartholin) are the homologues of the bulbo-urethral glands in the male. They consist of two small, round or oval bodies of a reddish-yellow colour, situated one on either side of the vaginal orifice, in contact with the posterior end of each lateral mass of the bulb of the vestibule. Each gland opens by means of a duct, about 2 cm. long, immediately laterally to the hymen, in the groove between its attached border and the labium minus.

THE MAMMÆ

The mammae or breasts secrete the milk, and are accessory glands of the generative system. They exist in the male as well as in the female, but in the former only in the rudimentary state. In the female they are two large hemispherical eminences lying within the superficial fascia on the front and

sides of the chest; each extends from the second rib above to the sixth rib below, and from the side of the sternum to near the mid-axillary line. In weight and size they differ at different periods of life, and in different individuals. Before puberty they are small, but they enlarge as the generative organs become more completely developed. They increase during pregnancy, and especially after delivery, and become atrophied in old age. The left mamma is generally a little larger than the right. The deep surface of each is nearly circular, flattened, or slightly concave, and has its long diameter directed upwards and lateralwards towards the axilla; it is separated from the fascia covering the Pectoralis major, Serratus anterior, and Obliquus externus abdominis by loose connective tissue. The subcutaneous surface of the mamma is convex, and presents, just below the centre, a small conical prominence, the papilla.

The **mammary papilla** or **nipple** is a cylindrical or conical eminence situated about the level of the fourth intercostal space. It is capable of

FIG. 1101.—A dissection of the lower half of the mamma during the period of lactation. (Luschka.)

undergoing a sort of erection from mechanical excitement, a change mainly due to the contraction of its muscular fibres. It is of a pink or brownish hue, its surface wrinkled and provided with secondary papillæ; and it is perforated by from fifteen to twenty orifices, the apertures of the lactiferous ducts. The base of the mammary papilla is surrounded by an *areola*. In the virgin the areola is of a delicate rosy hue; about the second month after impregnation it enlarges and acquires a darker tinge, and as pregnancy advances it may assume a dark brown, or even black colour. This colour diminishes as soon as lactation is over, but is never entirely lost. These changes in the colour of the areola are of importance in forming a conclusion in a case of suspected first pregnancy. Near the base of the papilla, and upon the surface of the areola, are numerous large sebaceous glands, the *areolar glands*, which become much enlarged during lactation, and present the appearance of small tubercles beneath the skin; they secrete a peculiar fatty substance, which serves as a protection to the integument of the papilla during the act of sucking. The mammary papilla consists of numerous vessels, intermixed with plain muscular fibres, which are principally arranged in a circular manner around the base, but a few fibres radiate from base to apex.

Structure (figs. 1101, 1102).—The mamma consists (a) of gland-tissue; (b) of fibrous tissue, connecting its lobes; and (c) of fatty tissue in the intervals between the lobes.

The subcutaneous tissue of the mamma presents numerous irregular processes which project towards the skin, and are joined to it by bands of connective tissue. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish colour, firm in texture, flattened from before backwards and thicker in the centre than at the circumference. It consists of numerous lobes, and these are composed of lobules, connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli which open into the smallest branches of the lactiferous ducts; these ducts unite to form larger ducts, and these end in single canals, corresponding with each of the chief subdivisions of the gland. The number of excretory ducts varies from fifteen to twenty; they are termed the *tubuli lactiferi*. They converge towards the areola, beneath which they form dilatations, or *ampullæ*, which serve as reservoirs for the milk. At the base of the papilla they become contracted, and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue containing longitudinal and transverse elastic fibres; they are lined by columnar epithelium resting on a basement membrane. The epithelium of the mamma differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling, the alveoli are very small and solid,

FIG. 1102.—A section through a portion of the mamma.

being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge, and the cells undergo rapid multiplication. At the commencement of lactation, the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk, as *colostrum corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with spherical nuclei, lining the basement membrane. When the gland is active, oil globules are found in the alveolar cells and are discharged into the lumen, constituting the milk-globules. When the acini are distended by the accumulation of the secretion the lining epithelium becomes flattened.

The fibrous tissue invests the entire surface of the mamma, and sends down septa between its lobes, connecting them together.

The fatty tissue covers the surface of the gland, and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and papilla.

Vessels and Nerves.—The arteries supplying the mamma are derived from the thoracic branches of the axillary, the intercostals, and the internal mammary. The veins describe an anastomotic circle round the base of the papilla, called by Haller the *circulus venosus*. From this, large branches transmit the blood to the circumference of the gland, and end in the axillary and internal mammary veins. The lymphatics are described on p. 788. The nerves are derived from the anterior and lateral cutaneous branches of the fourth, fifth, and sixth thoracic nerves.

Applied Anatomy.—The ducts descending from the mammary papilla radiate through the gland, and when an incision is made into the breast the scalpel should be directed radially, from the centre to the periphery, so that it may not pass across the ducts. A milk duct may become obstructed and distended, forming a tumour known as a *galactocoele*. Abscess frequently occurs about the mamma, more often in women who are lactating, especially in those who have cracks or fissures about the papilla. The abscess may be between the septa, in the gland-tissue itself, or it may lie beneath the skin by the side of the papilla and superficial to the mamma, or it may form beneath the mamma, between it and the deep fascia. Free incision, radiating from the papilla, is required in such cases.

Cystic formation of many different kinds is commonly seen in the mamma; in some cases it is due to dilatation of the larger ducts or of the lymph-spaces throughout the gland; in others the cysts occur in new growths of the mamma, or as the result of obstruction of the smaller ducts by chronic inflammatory processes.

Malignant growths are seen more often in the mamma than in any other organ; they are of great variety, but the commonest is the spheroidal-celled cancer, the cells of which are intermingled with a varying amount of fibrous tissue. A hard contracting tumour-mass results, which drags on the fibrous septa between the lobes so that fixation or retraction of the papilla ensues, and sooner or later the malignant infiltration invades the surrounding gland-tissues, the skin, the deep fascia and Pectorales, and even the chest-wall and pleura. The lymph-glands beneath the Pectorales and those situated towards the apex of the axilla become early involved with secondary malignant deposit, and later

the supraclavicular glands enlarge. In other cases the mediastinal glands may be involved, when the disease is situated on the medial side of the papilla.

The operation for removal of a mamma affected with malignant disease should be an extensive procedure, with the object of extirpating all fascial planes and lymphatic structures that may become infected. The incision commences below, over the upper part of the sheath of the Rectus, encloses the mamma by an ellipse, and is then continued on towards the apex of the axilla. The skin is reflected on both sides of the incision; anteriorly, till the sternum is reached, and posteriorly to the posterior boundary of the axilla. The origin of the sternal portion of the Pectoralis major is then divided and turned outwards. The Pectoralis minor is next seen, and its origin is then divided in a similar manner. The whole of the muscular and fascial planes of the front of the chest are thus separated *en masse*, carrying with them the mamma and the skin covering it. The insertions of the two Pectorales have next to be divided, and finally the axillary lymph-glands and fat are removed from the axillary vessels in one piece with the mass of tissue already detached. This is done by first freely exposing the whole length of the axillary vein and then, with a blunt instrument, peeling the structures off the vein from above downwards, from the point where they are crossed by the Subclavius muscle to the lower border of the axilla. In this part of the operation many branches of both vein and artery require ligature. The only thing which then remains to be divided is the deep fascia along the posterior axillary wall. The wound is then closed, drainage is provided, and firm pressure is applied with the dressings. It will be noted that the clavicular portion of the Pectoralis major is left intact, as it is of considerable service for the subsequent movements of the arm, the utility of which is but slightly impaired.

THE DUCTLESS GLANDS

The ductless glands are secreting structures which do not possess ducts through which their secretions may be discharged. The materials which they elaborate are termed *internal secretions*, and are conveyed into the blood by the veins or by the lymphatics.

The ductless glands consist of (a) the thyroid, parathyroids, thymus, spleen, suprarenal glands, glomera carotica, and glomus coccygeum (which will be described in this section); (b) the lymph-glands (described in the section on Angiology); and (c) the pineal gland and hypophysis cerebri (described in the section on Neurology).

THE THYROID GLAND (fig. 1103)

The thyroid gland is a highly vascular organ, situated at the front and sides of the lower part of the neck, opposite the fifth, sixth and seventh cervical vertebrae. It is ensheathed by the pretracheal layer of the fascia colli, and consists of right and left lobes connected across the middle line by a narrow portion, the *isthmus*. Its weight is somewhat variable, but is usually about 30 gm. It is slightly heavier in the female, in whom it becomes enlarged during menstruation and pregnancy.

The lobes are conical in shape, the apex of each being directed upwards and laterally as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downwards, and is on a level with the fifth or sixth tracheal ring. Each lobe is about 5 cm. long; its greatest width is about 3 cm., and its thickness about 2 cm. The lateral or superficial surface is convex, and covered by the skin, the superficial and deep fascia, the Sternocleidomastoideus, the superior belly of the Omohyoideus, the Sternohyoideus and Sternothyroideus, and beneath the last muscle by the pretracheal layer of the deep fascia, which forms a capsule for the gland. The medial surface is moulded over the thyroid and cricoid cartilages, the trachea, the Constrictor pharyngis inferior and posterior part of the Cricothyroideus, the oesophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent nerves. The posterior surface overlaps the common carotid artery, and, as a rule, the parathyroids. The anterior border is thin, and inclines obliquely from above downwards towards the middle line of the neck.

The *isthmus* connects together the lower thirds of the lobes ; it measures about 1.25 cm. transversely, and the same vertically, and usually covers the second and third rings of the trachea. Its situation and size present, however, many variations. It is covered by the skin and fascia, and close to the middle line, on either side, by the *Sternothyroideus*. Across its upper border runs an anastomotic branch uniting the two superior thyroid arteries ; at its lower border are the inferior thyroid veins. Sometimes the isthmus is altogether wanting.

A third lobe, of conical shape, called the *pyramidal lobe*, frequently arises from the upper part of the isthmus, or from the adjacent portion of either

FIG. 1103.--The thyroid gland and its relations.

lobe, but most commonly the left, and ascends as far as the hyoid bone. It is occasionally quite detached, or may be divided into two or more parts.

A fibrous or muscular band is sometimes found attached, above, to the body of the hyoid bone, and below, to the isthmus of the gland, or its pyramidal lobe ; when muscular, it is termed the *Levator glandulae thyroideae*.

Small detached portions of thyroid tissue are sometimes found in the vicinity of the lateral lobes or above the isthmus ; they are called *accessory thyroid glands*.

Structure.—The thyroid gland is closely invested by a thin capsule of connective tissue, which sends incomplete septa into its substance, dividing it into masses of irregular form and size. The gland is of a brownish-red colour, and is made up of a number of closed vesicles, just visible with the naked eye, containing a yellow glairy fluid, and separated from each other by intermediate connective tissue (fig. 1104).

The vesicles of the thyroid of the adult animal are generally closed spherical sacs ; but in some young animals (e.g. dogs) they are more or less tubular and branched. Each is lined by a single layer of cubical epithelium. There does not appear to be a basement membrane, so that the epithelial cells are in direct contact with the connective tissue reticulum which supports the acini. The vesicles are of various sizes, and contain a viscid, homogeneous, semi-fluid, slightly yellowish, colloidal material ; red corpuscles are found in it in various stages of disintegration and decolorisation, the yellow tinge being probably due to hæmoglobin, which is set free from the coloured corpuscles. The colloid

material contains an iodine compound, *iodothylin*, and, when coagulated by hardening reagents, is readily stained by eosin and other dyes. It passes out between the cubical cells and is absorbed into the blood or lymph.

Vessels and Nerves.—The *arteries* supplying the thyroid gland are the superior and inferior thyroid arteries and sometimes an additional branch (*a. thyroidea ima*) from the innominate artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The *veins* form a plexus on the surface of the gland and on the front of the trachea; from this plexus the superior, middle, and inferior thyroid veins arise; the superior and middle end in the internal jugular vein, the inferior in the innominate vein. The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymphatics which surround a greater or smaller part of the circumference of the vesicle. The *lymphatic vessels* run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland; they may contain colloid material. They end in the thoracic duct and the right lymphatic trunk. The *nerves* are derived from the middle and inferior cervical ganglia of the sympathetic.

Applied Anatomy.—An enlargement of the thyroid gland is called a *goitre*. The swelling may take the form of a diffuse hypertrophy of the whole gland, giving rise to the *parenchymatous goitre*, this being mainly due to the hypertrophy of the thyroid follicles

FIG. 1104.—A section through the thyroid gland of a sheep. $\times 100$.

themselves; in other cases a *fibroid* form of goitre is produced owing to the increase in the interstitial connective tissue; in others, again, the vascular changes may preponderate, and many large pulsating vessels may be present. Much more commonly, however, the enlargement is due to adenomatous new growth in the substance of the thyroid; these tumours are usually innocent, and tend to destroy life only by pressure on the air-passages. A single tumour is the rule, but in some instances a very large number may be present. They tend to show marked mucoid degeneration, and so become converted into cystadenomata, and finally into what appear to be simple cysts. These tumours may attain an enormous size and may involve practically the whole gland. Malignant tumour-growth more rarely attacks the organ.

When a goitre continues to grow, and especially when there are commencing symptoms of tracheal pressure, operative interference becomes necessary. This is not difficult, if an encapsulated tumour is to be dealt with, provided the anatomical layers covering it are remembered. In such a case it is necessary to make an incision suited to the size and situation of the tumour, and having divided the deep cervical fascia, to retract the Sternocleidomastoideus or divide it if necessary. The Sternohyoideus and Sternothyroideus next require division, or in some cases their fibres may be separated and drawn asunder, and beneath is found the ensheathing capsule derived from the pre-tracheal fascia; this requires division, and exposes the true capsule of the thyroid gland. In the case of an adenoma or cyst, this true capsule then needs incision before the tumour can be effectually shelled out, and this is usually accomplished with very little hæmorrhage, and without any of the main vessels of the gland requiring ligature.

Partial extirpation of the thyroid, viz. the removal of one lateral lobe with division of the isthmus, may be required in cases of parenchymatous goitre, and in the diffuse form of adenomatous disease. It is a more radical proceeding, and carries with it a much greater risk from hæmorrhage; there is also a danger of wounding the recurrent nerve. The whole gland must never be removed, as such a procedure is followed by the development of myxædema. In hemithyroidectomy a free incision is indicated—dividing

muscles, if necessary—to expose the true gland capsule, but at the same time avoiding injury to the large vessels which lie beneath it. The superior and inferior pedicles containing the respective thyroid arteries are then isolated and clamped on either side and divided between the clamps. The half gland is then turned over towards the middle line, and the isthmus ligatured and divided. Some venous bleeding is apt to occur from connexions with the tracheal veins, and must be stopped. The pedicles are then securely ligatured and the wound closed. In dealing with the inferior thyroid artery, the position of the recurrent nerve must be borne in mind, so as not to ligature or divide it. Temporary aphonia not uncommonly follows from bruising of the nerve, and if nothing more serious has occurred soon passes off.

THE PARATHYROID GLANDS

The parathyroid glands are small brownish-red bodies, situated as a rule between the posterior borders of the lateral lobes of the thyroid gland and its capsule. They measure on an average about 6 mm. in length, and from 3 mm. to 4 mm. in breadth, and usually present the appearance of flattened oval discs. They are divided, according to their situation, into *superior* and *inferior*. The superior, usually two in number, are the more constant in position, and are situated one on either side, at the level of the lower border of the cricoid cartilage, behind the junction of the pharynx and œsophagus. The inferior, also usually two in number, may be applied to the lower edge of the lateral lobes of the thyroid gland, or placed at some little distance below the thyroid gland, or found in relation to one of the inferior thyroid veins.*

In man, they number four as a rule; fewer than four were found in less than 1 per cent. of over a thousand persons (Peperé †) but more than four in over 33 per cent. of 122 bodies examined by Civalleri. In addition, numerous minute islands of parathyroid tissue may be found scattered in the connective tissue and fat of the neck round the parathyroid glands proper, and quite distinct from them.

Structure.—Microscopically the parathyroid glands consist of intercommunicating columns of cells supported by connective tissue containing a rich supply of blood-capillaries. Most of the cells are clear, but some, larger in size, contain oxyphil granules. Vesicles containing colloid have been described as occurring in the parathyroids.

Applied Anatomy.—No doubt the parathyroid glands produce an internal secretion essential to the well-being of the human economy; but it is still a matter of dispute what symptoms of disease are produced by their removal and suppression of their secretion. Peperé believes that they show signs of exceptional activity during pregnancy, and that parathyroid insufficiency is a main factor in the production of tetany in infants and adults, of eclampsia, and of certain sorts of fits.

THE THYMUS (fig. 1105)

The thymus is a temporary organ, attaining its largest size at the time of puberty (Hammar), when it ceases to grow, gradually dwindles, and almost disappears. If examined when its growth is most active, it will be found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the thorax, partly in the neck, and extending from the fourth costal cartilage upwards, as high as the lower border of the thyroid gland. It is covered by the sternum, and by the origins of the Sternohyoidei and Sternothyroidei. Below, it rests upon the pericardium, being separated from the aortic arch and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sternohyoidei and Sternothyroidei. The two lobes generally differ in size; they are occasionally united, so as to form a single mass; and sometimes separated by an intermediate lobe. The thymus is of a pinkish-grey colour, soft, and lobulated on its surfaces. It is about 5 cm. in length, 4 cm. in breadth below, and about 6 mm. in thickness. At birth it weighs about 15 gm.; at puberty, between 35 and 40 gm.

† Consult *Le Ghiandole paratiroides*, by A. Peperé, Turin, 1906.

FIG. 1105.—The thymus of a full-time fœtus, exposed *in situ*.

FIG. 1106.—The minute structure of the thymus. A follicle of the injected thymus of a calf, four days old. Slightly diagrammatic. Magnified about 50 diameters. The large vessels are disposed in two rings, one of which surrounds the follicle, the other lies just within the margin of the medulla. (Watney.)

* A. and B. From the thymus of a camel, examined without the addition of any reagent. Magnified about 400 diameters. A. Large colourless cell, containing small oval masses of haemoglobin. Similar cells are found in the lymph-glands, spleen, and medulla of bone. B. Coloured blood-corpuscles.

Structure.—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue; the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size and are made up of a number of small nodules or follicles, which are irregular in shape and are more or less fused together, especially towards the interior of the gland. Each follicle is from 1 mm. to 2 mm. in diameter and consists of a cortical and a medullary portion; it is enclosed in a connective tissue capsule, from which septa pass into its substance, but do not extend as far as the medullary portion of the follicle. The cortical portion is mainly composed of lymphocytes, supported by a network of finely branched cells, which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the medullary portion the reticulum is coarser than in the cortex, the lymphoid cells are relatively fewer in number, and there are found peculiar nest-like bodies, the concentric corpuscles of Hassall. These corpuscles are composed of a central mass, consisting of one or more granular cells, and of a capsule which is formed of concentrically arranged epithelioid cells (fig. 1106). Eosinophil and polymorphonuclear leucocytes are also found in the gland.

Each follicle is surrounded by a vascular plexus, from which vessels pass into the interior, and radiate from the periphery towards the centre, forming a second zone just within the margin of the medullary portion. In the centre of the medullary portion there are very few vessels, and they are of minute size (fig. 1106).

Watney observed that hæmoglobin is found in the thymus, either in cysts or in cells situated near to, or forming part of, the concentric corpuscles. This hæmoglobin occurs as granules or as circular masses exactly resembling coloured blood-corpuscles. He has also discovered, in the lymph issuing from the thymus, similar cells to those found in the gland, and, like them, containing hæmoglobin in the form of either granules or masses. From these facts he arrives at the conclusion that the gland is one source of the coloured blood-corpuscles. More recently Schaffer has observed actual nucleated red blood-corpuscles in the thymus.

Vessels and Nerves.—The arteries supplying the thymus are derived from the internal mammary, and from the superior and inferior thyroids. The veins end in the left innominate vein, and in the thyroïd veins. The lymphatics are described on p. 730. The nerves are exceedingly minute; they are derived from the vagi and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.

Applied Anatomy.—Sudden death—'thymus death'—with heart-failure, and with or without acute respiratory embarrassment, has been recorded in a number of infants and children in whom the thymus was considerably enlarged, and the lymphatic tissues throughout the body showed general hypertrophy, but who showed no other evidence of disease. Such deaths have often occurred during the administration of anæsthetics, particularly chloroform. How far the enlarged thymus was responsible for the death of these patients, and, if it was responsible, how far its action was mechanical, are points that have been much disputed. Short of producing this sudden death, it appears that thymic enlargement may cause attacks of respiratory stridor, or noisy and difficult breathing, and spasmodic attacks of asthma—'thymic asthma'—which may be frequently repeated and may even result in death. Primary tumours of the thymus are rare forms of mediastinal new growth, and are usually sarcomas.

THE SPLEEN (LIEN)

The spleen is situated principally in the left hypochondriac region, but its superior extremity extends into the epigastric region; it lies between the fundus of the stomach and the Diaphragm. It is the largest of the ductless glands, and is of an oblong, flattened form, soft, of very friable consistence, highly vascular, and of a dark purplish colour.

Relations.—The diaphragmatic surface is convex, smooth and is directed upwards, backwards, and to the left, except at its upper end, where it is directed slightly medialwards. It is in relation with the under surface of the Diaphragm, which separates it from the ninth, tenth, and eleventh ribs of the left side, and the intervening lower border of the left lung and pleura.

The visceral surface (fig. 1107) is divided by a ridge into an anterior or gastric, and a posterior or renal portion.

The gastric surface, which is directed forwards, upwards, and medialwards, is broad and concave, and is in contact with the posterior wall of the stomach; and below this with the tail of the pancreas. It presents near its medial border a long fissure, termed the *hilum*. This is pierced by several irregular apertures for the entrance and exit of vessels and nerves.

The renal surface is directed medialwards and downwards. It is somewhat flattened, is considerably narrower than the gastric surface, and is in relation

with the upper part of the anterior surface of the left kidney and occasionally with the left suprarenal gland.

The *superior extremity* is directed towards the vertebral column, where it lies on a level with the eleventh thoracic vertebra. The *lower extremity* or *colic surface* is flat, triangular in shape, and rests upon the left flexure of the colon and the phrenicocolic ligament, and is generally in contact with the tail of the pancreas. The *anterior border* is free, sharp, and thin, and is often notched near its lower end; it separates the diaphragmatic from the gastric surface. The *posterior border*, blunter and more rounded than the anterior, separates the renal from the diaphragmatic surface; it corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left

FIG. 1107.—The visceral surface of the spleen.

kidney. The *intermediate margin* is the ridge which separates the renal and gastric surfaces. The *inferior border* separates the diaphragmatic from the colic surface.

The spleen is almost entirely surrounded by peritoneum, which is firmly adherent to its capsule. It is in position by two folds of this membrane. One, the *phrenicocolic ligament*, is derived from the peritoneum where the wall of the general peritoneal cavity comes into contact with the omental bursa between the left kidney and the spleen, the lienal vessels pass between its two layers (fig. 1003). The other fold, the *gastrolieal ligament*, is also formed of two layers, derived from the wall of the general peritoneal cavity and the omental bursa respectively, where they meet between the spleen and stomach (fig. 1003); the short gastric and left gastro-epiploic branches of the lienal artery run between its two layers. The lower end of the spleen is supported by the phrenicocolic ligament (p. 1096).

The size and weight of the spleen vary at different periods of life, in different individuals, and in the same individual under different conditions. In the *adult*, it is usually about 12 cm. in length, 7 cm. in breadth, and 3 or 4 cm. in thickness, and weighs about 200 gm. The size of the spleen slowly increases during digestion, and varies according to the state of nutrition of the body, being large in highly fed, and small in starved, animals. In malarial fever it is greatly enlarged, and may weigh as much as 2 kilos.

Frequently in the neighbourhood of the spleen, and especially in the gastrolial ligament and greater omentum, small encapsulated nodules of splenic tissue may be found, either isolated or connected to the spleen by thin bands of splenic tissue. They are known as *accessory spleens*.

Structure.—The spleen is invested by two coats; an external serous and an internal fibro-elastic coat.

The *external or serous coat* is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the hilum and along the lines of reflection of the phrenicolial and gastrolial ligaments.

The *fibro-elastic coat or tunica propria* invests the organ, and at the hilum is reflected inwards upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, *trabeculae* (fig. 1108), are given off in all directions; these unite to form the framework of the spleen, in the interspaces of which is contained the *splenic pulp*.

FIG. 1108.—A transverse section through the spleen, showing the trabecular tissue and the splenic vein and its tributaries.

The fibro-elastic coat, the sheaths of the vessels, and the trabeculae, are composed of white, and yellow elastic, fibres, the latter predominating. It is owing to the presence of the elastic tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents there is a small amount of non-striped muscular fibre. In some mammals (e.g. dog, pig, and cat) the trabeculae consist chiefly of muscular tissue.

The *splenic pulp* is a soft mass of a dark reddish-brown colour; it consists of a fine reticulum of fibres, continuous with those of the trabeculae, to which are applied flat, branching cells. The meshes of the reticulum are filled with blood, in which, however, the white corpuscles are found to be in larger proportion than they are in ordinary blood. Large, rounded cells, termed *splenic cells*, are also seen; these are capable of amoeboid movement, and often contain pigment and red blood corpuscles in their interior. The cells of the reticulum each possess a round or oval nucleus, and like the splenic cells they may contain pigment granules in their cytoplasm; they do not stain deeply with carmine, and in this respect differ from the cells of the Malpighian bodies. In the young spleen giant cells may be found, each containing numerous nuclei or one compound nucleus. Nucleated red blood corpuscles have also been found in the spleen of young animals.

Blood-vessels of the spleen.—The lienal artery is remarkable for its large calibre in proportion to the size of the organ, and also for its tortuous course. It divides into six or more branches, which enter the hilum of the spleen and ramify throughout its substance (fig. 1109) receiving sheaths from an involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ, from within outwards, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular

sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

FIG. 1109.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.

The *arterioles* differ in structure from the larger arterial vessels in that their *outer coat consists of lymphoid tissue*. This coat exhibits localized spheroidal thickenings, termed the *Malpighian bodies* of the spleen (fig. 1110). These bodies vary in size from about 0.25 mm. to 1 mm. in diameter. In transverse sections, the artery, in the majority of cases, is found in an *eccentric position*. The Malpighian bodies are visible to the

FIG. 1110.—Transverse section of a portion of the spleen.

naked eye on the surface of a fresh section of the organ, appearing as minute semi-opaque dots of a whitish colour in the dark substance of the pulp. The reticulum of the adenoid tissue is made up of extremely fine fibrils, and is comparatively open in the centre of the body, but closer at its periphery.

The arterioles end by opening freely into the splenic pulp; their walls become much attenuated, they lose their tubular character, and the endothelial cells ramify, their

processes being directly connected with those of the reticular cells of the pulp (fig. 1111). The blood thus finds its way into the interstices of the reticulated tissue of the splenic pulp. It is then collected by the rootlets of the veins, which begin much in the same way as the arteries end. The connective tissue corpuscles of the pulp arrange themselves in rows, in such a way as to form an elongated space or sinus. They become elongated and spindle-shaped, and overlap each other at their extremities, and thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings, which are due to minute elastic fibrils arranged in a circular manner around the sinus. Thus the channel obtains an external investment, and gradually becomes converted into a small vein, which after a short course acquires a coat of ordinary connective tissue, lined by a layer of flattened epithelial cells continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones; these do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form six or more branches, which emerge from the hilum, and, uniting, constitute the lienal vein, the largest radicle of the portal vein.

The veins are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The lymphatics are described on p. 732.

The nerves are derived from the coeliac plexus and are chiefly non-medullated. They are distributed to the blood-vessels and to the smooth muscle of the capsule and trabeculae.

FIG. 1111.- A section of the spleen, showing the termination of a small blood-vessel.

Applied Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connexions. It may be ruptured by direct or indirect violence; torn by a broken rib; or injured by a punctured or gunshot wound. When the organ is enlarged, the chance of rupture is increased. The great risk is hæmorrhage, owing to the vascularity of the organ and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due, in a great measure, to the contractile power of the capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear, and the symptoms indicate danger to life, laparotomy must be performed, and the spleen removed.

The spleen may become enormously enlarged in certain diseased conditions, such as ague, leucæmia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma, as a part of a general blood-disease. In these cases the tumour may fill a considerable part of the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine new growth.

The spleen is sometimes the seat of cystic tumours, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken, if there are no adhesions between the spleen and abdominal wall, to prevent the escape of any of the pus into the peritoneal cavity.

Extirpation of the spleen has been performed for wounds or injuries, in floating spleen, in simple hypertrophy, in leucæmic enlargement (but the operation is now considered unjustifiable in this condition), and in the case of enlargement due to certain obscure parasitic infections met with in hot climates. The incision is best made in the left semi-lunar line; the spleen is isolated from its surroundings and delivered from the abdomen; the pedicle is then transfixed and ligatured in two portions.

SUPRARENAL GLANDS (figs. 1112, 1113)

The suprarenal glands are two small flattened bodies of a yellowish colour, situated at the posterior part of the abdomen, behind the peritoneum, and immediately above and in front of the upper end of either kidney; hence their name. They are surrounded by areolar tissue containing a considerable amount of fat. The right one is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left is more semilunar, usually larger and

FIG. 1112.—The suprarenal glands. Viewed from the front.

placed at a higher level than the right. They measure from 30 mm. to 50 mm. in height; about 30 mm. in breadth, and from 4 mm. to 6 mm. in thickness. The average weight of each is from 3 gm. to 4 gm.

Relations.—The *right suprarenal gland* is situated behind the inferior vena cava and right lobe of the liver, and in front of the Diaphragm and upper end of the right kidney. It is roughly triangular in shape; its base, directed downwards, is in contact with the medial and anterior surfaces of the upper end of the right kidney. Its *anterior surface* looks forwards and lateralwards,

FIG. 1113.—The suprarenal glands. Viewed from behind.

and has two areas: a medial, narrow and non-peritoneal, which lies behind the inferior vena cava; and a lateral, somewhat triangular, in contact with the liver. The upper part of the latter surface is devoid of peritoneum, and is in relation with the bare area of the liver near its lower and medial angle, while its inferior portion may be covered by peritoneum, reflected on to it from the inferior layer of the coronary ligament; occasionally the duodenum overlaps the inferior portion. A little below the apex, and near the anterior border of the gland, is a short furrow termed the hilum, from which the right suprarenal vein emerges to join the inferior vena cava. Its *posterior surface*

is divided into upper and lower parts by a curved ridge; the upper, slightly convex, rests upon the Diaphragm; the lower, concave, is in contact with the upper end and the adjacent part of the anterior surface of the kidney.

The *left suprarenal gland*, slightly larger than the right, is crescentic in shape, its concavity being adapted to the medial border of the upper part of the left kidney. Its medial

FIG. 1114.—A section through a part of a suprarenal gland. (Magnified.)

border is convex, its lateral, concave; its upper end is narrow, its lower, rounded. Its *anterior surface* has two areas: an upper, covered by the peritoneum of the omental bursa, which separates it from the cardiac end of the stomach and sometimes from the superior extremity of the spleen; and a lower, which is not covered by peritoneum, but is in contact with the pancreas and lienal artery. Near the lower part of the anterior surface is the hilum, which is directed downwards and forwards. From it the left suprarenal vein emerges to join the left renal vein. Its *posterior surface* is divided into two areas by a vertical ridge; the lateral area rests on the kidney, the medial and smaller, on the left crus of the Diaphragm.

Small *accessory suprarenals* are often found in the connective tissue round the suprarenals.

Structure.—The suprarenal gland is closely invested by a capsule of connective tissue from which trabeculae pass into the substance of the gland; the capsule may contain smooth muscle fibres. On section, the gland is seen to consist of two portions (fig. 1114): an external or cortical, and an internal or medullary. The former constitutes the larger part of the organ, and is of a deep yellow colour; the medullary substance is soft, pulpy, and of a dark red or brown colour.

The *cortical portion* consists of a fine connective tissue network, in which is imbedded the glandular epithelium. The epithelial cells are polyhedral in shape and possess rounded nuclei; many of the cells contain coarse granules, others lipid globules. Owing to differences in the arrangement of the cells three distinct zones can be made out: (1) The *zona glomerulosa*, situated beneath the capsule, consists of cells arranged in rounded groups, with here and there indications of an alveolar structure. (2) The *zona fasciculata*, continuous with the zona glomerulosa, is composed of columns of cells arranged in a radial manner; these cells contain finer granules and in many instances globules of lipid material. (3) The *zona reticularis*, in contact with the medulla, consists of cylindrical columns of cells irregularly arranged; these cells often contain pigment-granules which give this zone a darker appearance than the rest of the cortex.

The *medullary portion* is extremely vascular, and is composed of a network of large cells, the interspaces containing large venous sinusoids. The cells forming the network are finely granular, and have an especial affinity for chromic salts, which stain them a brown colour. Such cells are therefore termed *chromaffin cells* (p. 101). This portion of the gland is richly supplied with non-medullated nerve-fibres, and here and there sympathetic ganglia are found.

The suprarenal gland is large in the foetus, owing to the great development of the inner layer of the cortex. This layer has been named the *boundary zone* by Elliott and Armour. Its cells contain no lipid granules. This zone disappears soon after birth and is absent in anencephalic foetuses.

In connexion with the development of the medulla from the sympathochromaffin tissue, it is to be noted that this portion of the gland secretes a substance, *adrenalin*, which has the property of stimulating all sympathetic nerve-endings.

Vessels and Nerves.—The arteries supplying the suprarenal glands are numerous and of comparatively large size; they are derived from the aorta, the inferior phrenic, and the renal. In the cortical part of the gland they break up into capillaries which end in the sinusoids of the medullary portion; the latter open into the veins near the centre of the medulla.

The *suprarenal vein* emerges from the hilum of the gland, and on the right side opens into the inferior vena cava, on the left into the renal vein.

The *lymphatics* end in the lumbar glands.

The *nerves* are exceedingly numerous, and are derived from the coeliac and renal plexuses, and, according to Bergmann, from the phrenic and vagus nerves. They enter the lower and medial part of the capsule, traverse the cortex, and end around the cells of the medulla. They have numerous small ganglia developed upon them in the medullary portion of the gland.

Applied Anatomy.—The suprarenal cortex is derived from the ectodermic epithelium of the Wolffian ridge, and is connected with the sexual glands; it is related to growth and development in some way, and is often found to be hypertrophied in patients with chronic kidney disease and high blood-pressure. The *medulla*, on the other hand, is neuro-ectodermal in origin, and closely connected with the sympathetic nervous system. When the suprarenal medulla is destroyed by tuberculosis, to which the glands are prone, or by the pressure of a new growth, the secretion of adrenalin becomes inadequate, and Addison's disease develops. Patients with Addison's disease become pigmented in various parts of the body, possibly from irritation of the sympathetic, and complain of great weakness, lack of energy, nausea, and severe attacks of vomiting. Their blood-

FIG. 1115.—A section of a part of a human glomus caroticum. (Schaper.) Highly magnified. (From Quain's Elements of Anatomy, Vol. II. Pt. I.)

Numerous blood-vessels are seen in section among the gland-cells.

pressure is low, the whole nervous system is depressed, and death follows after a period of months or years, usually from asthenia. Tumours derived from the suprarenal itself, or from misplaced suprarenal 'rests' occurring in such organs as the kidney or liver, may be either benign or malignant, and are classed together under the name 'hypernephroma.' In children the malignant hypernephroma is often associated with obesity and precocity. The benign hypernephroma, or suprarenal adenoma, appears to produce no symptoms except those due to its slow enlargement.

The *glomera carotica* (carotid bodies), two in number, are situated one on either side of the neck, behind the common carotid artery at its point of bifurcation into the external and internal carotid trunks. They are reddish-brown in colour and oval in shape, the long diameter measuring about 5 mm.

Structure.—Each glomus is invested by a fibrous capsule and consists largely of spherical or irregular masses of chromaffin cells (fig. 1115)—the masses being more or less isolated from one another by septa which extend inwards from the deep surface of the capsule. The cells are polyhedral in shape, and each contains a large nucleus imbedded in finely granular protoplasm. Numerous nerve-fibres, derived from the sympathetic plexus on the carotid artery, are distributed throughout the organ, and a network of large sinusoidal capillaries ramifies amongst the cells.

The *glomus coccygeum* (coccygeal body) is placed in front of, or immediately below, the tip of the coccyx. It is about 2.5 mm. in diameter and is irregularly oval in shape; several smaller nodules are found around or near the main mass.

Structure.—The glomus coecygeum consists of irregular masses of round or polyhedral cells (fig. 1116), the cells of each mass being grouped around a dilated sinusoidal capillary vessel. Each cell contains a large round or oval nucleus, the protoplasm surrounding which is clear and is not stained by chromic salts.*

FIG. 1116.—Section of an irregular nodule of the glomus coecygeum. $\times 85$.
(Sertoli.) (From Quain's Elements of Anatomy, Vol. II. Pt. I.)

The section shows the fibrous covering of the nodule, the blood-vessels within it, and the epithelial cells of which it is constituted.

Besides the ductless glands mentioned, reference may be made to a pair of small bodies, the **aortic bodies of Zuckerkandl**. These are found in the embryo, and persist until shortly after birth; they lie one on either side of the abdominal aorta between the superior mesenteric and common iliac arteries (p. 101). They consist essentially of masses of polygonal or cuboidal chromaffin cells imbedded in a wide-meshed capillary plexus.

SURFACE ANATOMY AND SURFACE MARKINGS

SURFACE ANATOMY OF THE HEAD AND NECK

Bones (fig. 1117).—The *external occipital protuberance* (inion) is situated behind, in the middle line, at the upper end of the nuchal furrow, and the *superior nuchal lines* run lateralwards from it, one on either side. Above these lines the vault

FIG. 1117.—Side view of head, showing surface relations of bones.

of the cranium is so thinly covered with soft structures that the form of this part of the head is almost that of the upper portion of the occipital, the parietal and the frontal bones. The superior nuchal lines run lateralwards to the mastoid portions of the temporal bones, from which the *mastoid processes* project downwards and forwards behind the auriculæ. The anterior and posterior borders, the apex, and the external surface of the mastoid process are available for surface examination; the anterior border lies immediately behind the concha, and the apex is nearly on a level with the lobule of the auricula. The *transverse process of the atlas* is deeply placed, about 1 cm. below and in front of the apex of the mastoid process. In front of the ear the *zygomatic arch* can be felt throughout its entire length; its narrow posterior end is situated a little above the level of the tragus; its broad

anterior end is continued into the zygomatic bone. The upper border of the arch is less distinct than the lower, but can be followed into the *superior temporal line*. Anteriorly, this line begins at the zygomatic process of the frontal bone as a curved ridge which runs at first forwards and upwards and then backwards on the frontal bone, separating the forehead from the temporal fossa. It then crosses the parietal bone, where, though less marked, it can generally be recognised. Finally, it curves downwards and forwards, and, passing above the opening of the external acoustic meatus, ends in the posterior root of the zygomatic arch.

Near the line of the greatest transverse diameter of the head are the *parietal tuberosities*, one on either side; further forwards, on the forehead, are the *frontal tuberosities*, which vary in prominence in different individuals and are sometimes unsymmetrical. Below the frontal tuberosities are the *superciliary arches*, which indicate the position of the frontal sinuses; they are absent in infancy, and are, as a rule, small in the female. In some cases the prominence of these arches is related to the size of the frontal sinuses, but frequently there is no such relationship. Between the superciliary ridges is a smooth, somewhat triangular area, the *glabella*, and below this is the *nasion* or frontonasal suture.

Below the nasion the *nasal bones*, scantily covered by soft tissues, can be traced to their junctions with the nasal cartilages, and on either side of the nasal bones the complete outline of the *orbital margin* can be made out. At the junction of the medial with the intermediate third of the supraorbital margin the *supraorbital notch*, when present, can be felt; near the medial end of the infraorbital margin is a little tubercle which serves as a guide to the position of the lacrimal sac. Below and lateral to the orbit, on either side, the *zygomatic bone* forms the prominence of the cheek; its posterior margin is easily felt, and on it just above the level of the lateral palpebral commissure is the *zygomatic tubercle*. A slight depression, about 1 cm. above this tubercle, indicates the position of the *zygomaticofrontal suture*. Below the orbit a considerable part of the anterior surface, and the whole of the alveolar process, of the *maxilla*, can be palpated. Almost the entire outline of the *mandible* can be recognised; the condyle lies in front of the tragus and below the zygomatic arch, and from it the posterior border of the ramus descends to the angle; from the angle to the symphysis the lower rounded border of the body of the bone is readily traced; the lower part of the anterior border of the ramus and the alveolar process can be made out without difficulty. In the receding angle below the chin is the *hyoid bone*, and the finger can be carried along the bone to the tip of its greater cornu, which is most readily appreciated by making pressure on one side of the bone, when the cornu of the opposite side is rendered prominent beneath the skin.

The transverse processes of the first, sixth, and seventh cervical vertebræ can be felt. That of the first is about 1 cm. below and in front of the mastoid process of the temporal bone; that of the sixth is opposite to, and that of the seventh a little below, the cricoid cartilage.

Joints and muscles.—The *temporomandibular articulation* is superficial and is situated below the posterior end of the zygomatic arch, in front of the external acoustic meatus. Its position can be ascertained by defining the condyle of the mandible; when the mouth opens, the condyle advances out of the mandibular fossa on to the articular tubercle of the temporal bone, and a depression is felt in the situation of the joint.

With the exceptions of the *Masseter* and *Temporalis* the outlines of the muscles of the head and face cannot be traced on the surface. The *Masseter* imparts fullness to the hinder part of the cheek; if firmly contracted, as when the teeth are clenched, its quadrilateral outline is plainly visible; its anterior border forms a prominent vertical ridge, behind which is a considerable fullness especially marked at the lower part of the muscle. The *Temporalis*, a fan-shaped muscle, fills the temporal fossa, and stands out in strong relief when in action. The muscles of the scalp are so thin that the contour of the skull is perceptible beneath them. Those of the face are small, covered by soft skin and often by a considerable layer of fat, and their outlines are therefore concealed; they serve, however, to round off and smooth prominent borders, and to fill up what would otherwise be unsightly angular depressions. Thus the *Orbicularis oculi* rounds off the prominent margin of the orbit, and the *Procerus* fills in the sharp depression below the glabella. In like manner the *labial muscles*, converging to the lips, and assisted by the superimposed fat, fill up the sunken hollow of the lower part of the face. When in action the

facial muscles produce the various expressions, and in addition throw the skin into numerous folds and wrinkles.

By the contraction of the *Platysma* the skin of the neck is thrown into oblique ridges parallel with the fasciuli of the muscle. The *Sternocleidomastoideus* has the most important influence on the surface form of the neck (figs. 1118, 1119). When the muscle is at rest its anterior border forms an oblique rounded edge ending below in the outline of the sternal head; the posterior border is only distinct for about 2 cm. or 3 cm. above the middle of the clavicle. When the muscle is contracted, the sternal head stands out as a sharply defined ridge, while the clavicular head is flatter and less prominent; between the two heads is a slight depression. The middle portion of the muscle appears as an oblique elevation with a thick,

FIG. 1118.—Anterolateral view of head and neck.

anterior border, best marked in its lower part. The sternal heads of the two muscles are separated by a V-shaped depression (jugular notch) in which are the *Sternohyoideus* and *Sternothyroideus*.

Above the hyoid bone, near the middle line, the anterior belly of *Digastricus* gives rise to a slight convexity.

The anterior border of the *Trapezius* produces a faint ridge running downwards and forwards from the superior nuchal line to the junction of the intermediate with the lateral third of the clavicle. Between the *Sternocleidomastoides* and the *Trapezius* is the posterior triangle of the neck, the lower part of which appears as a shallow concavity—the supraclavicular fossa. In this fossa, the inferior belly of *Omohyoideus*, when in action, causes a cord-like elevation a little above and almost parallel to the clavicle.

Arteries.—The positions of several of the larger arteries can be ascertained from their pulsations.

The *subclavian artery* is felt on making pressure downwards, backwards, and medialwards behind the lateral margin of the clavicular head of the *Sternocleidomastoides*; its *transverse cervical* branch may be detected parallel to, and about a finger's breadth above, the clavicle. The *common* and *external carotid arteries*

can be recognised immediately beneath the anterior edge of the Sternocleidomastoideus, and the *external maxillary artery* traced over the inferior border of the mandible at the anterior edge of the Masseter. The pulsation of the *occipital artery* may be felt about 3 cm. or 4 cm. laterally to the external occipital protuberance, and that of the *posterior auricular* in the groove between the mastoid process and the auricula. The course of the *superficial temporal artery* can be readily followed upwards across the posterior end of the zygomatic arch to a point about 4 cm. above the arch, where it divides into its frontal and parietal branches; the pulsation of the frontal branch is frequently visible on the side of the forehead. The *supra-orbital artery* can usually be detected immediately above the supraorbital notch or foramen.

Larynx and Trachea.—In the receding angle below the chin, the hyoid bone (p. 1210), situated opposite the lower part of the third cervical vertebra, can easily

FIG. 1119.—Front view of neck.

be made out. A finger's-breadth below it, is the laryngeal prominence (pomum Adami) of the thyroid cartilage; the space between the hyoid bone and the thyroid cartilage is occupied by the thyrohyoid membrane. The outlines of the alæ and cornua of the thyroid cartilage are readily palpated; below this cartilage is a depression corresponding to the middle cricothyroid ligament. The level of the vocal folds (true vocal cords) corresponds to the middle of the anterior margin of the thyroid cartilage. The anterior part of the cricoid cartilage forms an important landmark on the front of the neck; it lies opposite the sixth cervical vertebra, and indicates the junctions of the pharynx with the œsophagus, and of the larynx with the trachea. Below the cricoid cartilage the trachea can be felt, but only in thin subjects are its rings distinguishable; as a rule there are seven or eight rings above the jugular notch of the sternum, and of these the second, third, and fourth are covered by the isthmus of the thyroid gland. The normal thyroid gland cannot be felt.

Submaxillary gland.—On either side of the neck the superficial portion of the submaxillary gland, as it lies partly under cover of the body of the mandible, can be palpated.

SURFACE MARKINGS OF SPECIAL REGIONS OF HEAD AND NECK

THE CRANIUM

Scalp.—The soft parts covering the upper surface of the skull form the scalp and comprise the following layers (fig. 1120): (1) skin, (2) subcutaneous tissue, (3) Occipitalis, Frontalis, and galea aponeurotica, (4) subaponeurotic tissue, (5) pericranium. The subcutaneous tissue consists of a close meshwork of fibres, the meshes of which contain fatty tissue; the fibres bind the skin and galea aponeurotica firmly together, so that when the Occipitalis or the Frontalis is in action the skin

FIG. 1120.—Diagrammatic section of scalp.

moves with the aponeurosis. The subaponeurotic tissue is much looser in texture, and permits the movement of the galea aponeurotica over the underlying pericranium.

Bony landmarks (fig. 1117).—In addition to the bony points already described, which can be determined by palpation, the following are utilised for surface markings:

Asterion.—The point of meeting of the lambdoidal, masto-occipital, and masto-parietal sutures; it lies 4 cm. behind and 12 mm. above the level of the auricular point.

Auricular point.—The centre of the orifice of the external acoustic meatus.

Bregma.—The meeting-point of the coronal and sagittal sutures; it lies at the point of intersection of the middle line of the scalp with a line drawn vertically upwards through the pre auricular point.

Lambda.—The point of meeting of the lambdoidal and sagittal sutures; it is in the middle line about 6.5 cm. above the inion.

Pre-auricular point.—A point on the posterior root of the zygomatic arch immediately in front of the orifice of the external acoustic meatus.

Pterion.—The point where the great wing of the sphenoid joins the sphenoidal angle of the parietal; it is situated 35 mm. behind, and 12 mm. above, the level of the frontozygomatic suture.

A line passing through the inferior margin of the orbit and the auricular point is known as *Reid's base-line*. The *lambdoidal suture* is indicated by the upper two-thirds of a line uniting the lambda to the tips of the mastoid processes. The *sagittal suture* is in the line joining the lambda to the bregma. The position of the *coronal suture* is represented by a line connecting the bregma with the centres of the zygomatic arches.

of the third with the fourth part (reckoning from the front) draw a line to the frontozygomatic suture; from the junction of the first with the second part a line to the auricular point. These two lines intersect at the Sylvian point, and the portion of the first line behind this point overlies the posterior ramus of the lateral cerebral fissure. The position of the posterior ramus can also be obtained by joining the Sylvian point to one 2 cm. below the summit of the parietal tuberosity. The anterior ascending ramus is marked by drawing a line upwards at right angles to the line of the posterior ramus for 2 cm., and the anterior horizontal ramus by a line of the same length drawn horizontally forwards—both from the Sylvian point. To define the *central sulcus* (fissure of Rolando) two points are taken; one 1.25 cm. behind the centre of the line joining the nasion andinion; the other

FIG. 1122.—Relations of the brain and middle meningeal artery to the surface of the skull.

1. Nasion. 2. Inion. 3. Lambda. 4. Lateral cerebral fissure. 5. Central sulcus. AA. Reid's base-line. B. Point for trephining over the anterior branch of the middle meningeal artery. C. Supra-mental triangle. D. Sigmoid bend of the transverse sinus. E. Point for trephining over the straight portion of the transverse sinus, exposing dura mater of both cerebrum and cerebellum. The outline of the cerebral hemisphere is indicated in blue; the course of middle meningeal artery in red.

at the intersection of the line of the posterior ramus of the lateral cerebral fissure with a line through the pre-auricular point at right angles to Reid's base-line. The upper 9 cm. of the line joining these two points overlies the central sulcus and forms an angle, opening forwards, of about 70° with the middle line of the scalp. An alternative method is to draw two perpendicular lines from Reid's base-line to the top of the head; one from the pre-auricular point and the other from the posterior border of the root of the mastoid process. A line from the upper end of the posterior line to the point where the anterior intersects the line of the posterior ramus of the lateral fissure indicates the position of the central sulcus. The *precentral* and *postcentral sulci* are nearly parallel with the central sulcus, and are situated about 15 mm. in front of, and behind, it respectively. The *superior frontal sulcus* is indicated by a line drawn from the junction of the upper with the middle third of the precentral sulcus, in a direction parallel with the longitudinal sulcus, to a point midway between the middle line of the forehead and the temporal line, 4 cm. above the supraorbital notch. The *inferior frontal sulcus* begins at the junction of the middle with the lower third of the precentral sulcus, and follows the course of the superior temporal line.

The horizontal limb of the *intraparietal sulcus* begins at the junction of the lower with the middle third of the postcentral sulcus and curves backwards parallel to the longitudinal fissure, midway between it and the parietal tuberosity; it then curves downwards to end midway between the lambda and the parietal tuberosity. The external part of the *parieto-occipital fissure* runs lateralwards at right angles to the longitudinal fissure for about 2.5 cm. from a point 5 mm. in front of the lambda. If the line of the posterior ramus of the lateral cerebral fissure be continued back to the longitudinal fissure, the last 2.5 cm. of it will indicate the position of the parieto-occipital fissure.

The *lateral ventricle* may be circumscribed by a quadrilateral figure. The upper limit is a horizontal line 5 cm. above the zygomatic arch; this defines the roof of the ventricle. The lower limit is a horizontal line 1 cm. above the zygomatic arch; it indicates the level of the end of the inferior cornu. Two vertical lines, one through the junction of the anterior with the middle third of the zygomatic arch, and the other 5 cm. behind the tip of the mastoid process, indicate the extent of the anterior cornu in front and the posterior cornu behind.

Vessels.—The anterior division of the *middle meningeal artery* crosses the inner surface of the sphenoidal angle of the parietal bone at a point 4 cm. behind the frontozygomatic suture and 4.5 cm. above the zygomatic arch. The posterior division can be reached 2.5 cm. above the auricular point.

The position of the *transverse sinus* is obtained by taking two lines: the first from the inion to a point 2.5 cm. behind the auricular point; the second from the anterior end of the first to the tip of the mastoid process. The second line corresponds roughly to that of the reflection of the skin from the cranial surface of the auricula, and its upper two-thirds represents the sigmoid part of the sinus. The first part of the sinus has a slight upward convexity, and its highest point is about 4 cm. behind and 1 cm. above the level of the auricular point. The width of the sinus is about 1 cm.

THE FACE

Air-sinuses (fig. 1123).—The frontal and maxillary sinuses vary so greatly in form and size that their surface markings must be regarded as only approximate.

FIG. 1123.—Outline of bones of face, showing position of frontal and maxillary sinuses.

To mark out the position of the *frontal sinus* three points are taken: one at the nasion, a second in the middle line 3 cm. above the nasion, and a third at the junction of the lateral with the intermediate third of the supraorbital margin. By joining these a triangular field is described which overlies the greater part of the sinus. The outline of the *maxillary sinus* is irregularly quadrilateral and is obtained by joining up the following points: (1) the lacrimal tubercle, (2) a point on the zygomatic bone at the junction of the inferior with the lateral margin of the orbit, (3) and (4) points on the alveolar process above the last molar and the second premolar teeth respectively.

External maxillary artery.—The course of this artery on the face may be indicated by a line starting from the lower border of the mandible at the anterior margin of the Masseter, and running at first forwards and upwards to a point 1 cm. laterally to the angle of the mouth, thence to the ala of the nose and upwards to the medial commissure of the eye (fig. 1124).

Trigeminal nerve.—The supratrochlear nerve crosses the supraorbital margin about 1 cm. from the middle line. The supraorbital, infraorbital, and mental branches of the trigeminal nerve emerge from the corresponding foramina on the face (fig. 1124). The supraorbital foramen is situated at the junction of the medial with the intermediate third of the supraorbital margin. A line drawn from this foramen to the lower border of the mandible, through the interval between the lower premolar teeth, passes over the infraorbital and mental foramina: the former lies about 1 cm. below the margin of the orbit, while the latter varies in position according to the age of the individual; in the adult it is midway between the upper and lower borders of the mandible, in the child it is nearer the lower border, while in the edentulous jaw of old age it is close to the upper margin.

The position of the sphenopalatine ganglion is indicated from the side by a point on the upper border of the zygomatic arch, 6 mm. from the temporal border of the zygomatic bone. The foramen ovale, which is the guide to the semilunar ganglion, lies opposite the anterior border of the neck of the mandible.

Parotid gland (fig. 1124). -- The upper border of the parotid gland corresponds to the posterior two-thirds of the lower border of the zygomatic arch; the posterior border to the front of the external acoustic meatus, the mastoid process, and the anterior border of Sternocleidomastoideus. The inferior border is indicated by a line from the tip of the mastoid process to the junction of the body and greater cornu of the hyoid bone. In front, the anterior border extends for a variable distance on the superficial surface of the Masseter. The surface marking for the *parotid duct* is a line drawn across the face about a finger's breadth below the zygomatic arch, i.e. from the lower margin of the concha to midway between the red margin of the lip and the ala of the nose; the duct ends opposite the second upper molar tooth and measures about 5 cm. in length.

FIG. 1124.—Outline of side of face, showing chief surface markings.

THE NOSE

The outlines of the nasal bones and the cartilages forming the external nose can be easily felt. The mobile portion of the nasal septum, formed by the medial crura of the greater alar cartilages and the skin, is easily distinguished between the nares. When the head is tilted back and a speculum introduced through one naris, the floor of the nasal cavity, the lower part of the nasal septum, and the anterior ends of the middle and inferior nasal conchæ can be examined. The opening of the nasolacrimal duct, which lies under cover of the front of the inferior nasal concha, is situated about 2.5 cm. behind the naris and 2 cm. above the floor of the nasal cavity.

THE MOUTH

The orifice of the mouth is bounded by the lips, and its angles usually correspond to the lateral borders of the canine teeth. In the middle of the outer surface of the upper lip is a shallow groove—the philtrum. When the lips are everted, a small fold of mucous membrane, termed the frenulum, is seen in the middle line of each, passing from the lip to the gum. By pulling the angle of the mouth outwards the mucous

membrane of the cheek can be inspected, and on this, opposite the second upper molar tooth, is the little papilla which marks the orifice of the parotid duct.

The upper surface of the tongue (fig. 1125) is convex and marked in the middle line by a shallow sulcus; its anterior two-thirds are rough and studded with papillæ; its posterior third is smoother and contains many muciparous glands and lymph-follicles; it is much more sensitive than the anterior papillary part. These two parts are separated by a V-shaped furrow, the *sulcus terminalis*, which is situated immediately behind the *papillæ vallatæ*.

FIG. 1125.—The mouth-cavity. The cheeks have been slit transversely and the tongue pulled forwards.

The mucous membrane on the under surface of the tongue (fig. 1126) is smooth and devoid of papillæ. In the middle line it extends to the floor of the mouth as a fold—the *frenulum*—the free edge of which runs forwards to the symphysis menti. The *ranine veins* are seen immediately beneath the mucous membrane on either side of the *frenulum*. On either side of the attachment of the *frenulum* to the floor of the mouth is a *papilla* on which the slit-like orifice of the *submaxillary duct* is seen. Running backwards and lateralwards from the orifice of the *submaxillary duct* is the *plica sublingualis*, produced by the upward projection of the *sublingual gland* which lies immediately beneath the mucous membrane. The *plica lingualis* serves also to indicate the lines of the *submaxillary duct* and *lingual nerve*; they lie on the medial side of the gland. At the back of the mouth is the *isthmus faucium*, bounded above by the *palatine velum*, from the free margin of which the *uvula* projects downwards in the middle line. On either side of the *isthmus* are the two *palatine arches*, the anterior formed by the *Glossopalatinus*

and the posterior by the Pharyngopalatinus. Between the two arches of either side is the palatine tonsil, with the small supratonsillar recess above it; the position

FIG. 1126.—The mouth cavity. The apex of the tongue is turned upwards, and on the right side a superficial dissection of its under surface has been made.

of the tonsil corresponds to the angle of the mandible. When the mouth is opened widely, a tense band--the pterygomandibular raphe--can be seen and felt laterally to the glossopalatine arch. Its lower end is attached to the mandible behind the last molar tooth, and immediately below and in front of this attachment the

FIG. 1127.—Front of nasal part of pharynx, as seen with the laryngoscope.

lingual nerve can be felt; the upper end of the raphe is fixed to the pterygoid hamulus. About 1 cm. anterior to the hamulus and 1 cm. medial to the third

upper molar tooth is the greater palatine foramen through which the greater palatine vessels and the anterior palatine nerve emerge. Behind the third upper molar tooth the coronoid process of the mandible is palpable.

By tilting the head well back a portion of the posterior pharyngeal wall, corresponding to the level of the second and third cervical vertebræ, can be seen

FIG. 1128.—Laryngoscopic view of interior of larynx.

through the isthmus faucium. On introducing the finger the anterior surfaces of the upper cervical vertebræ can be felt through the thin muscular wall of the pharynx; if the finger be hooked round the palatine velum, the choana, the posterior ends of the middle and inferior nasal conchæ, and the pharyngeal ostia of the auditory (Eustachian) tubes can be distinguished. The level of the choana is that of the atlas, while the palatine velum is opposite the body of the epistropheus.

With the laryngoscope the following structures can be seen. In the nasal part of the pharynx (fig. 1127), the choana, the nasal septum and conchæ, and the pharyngeal ostia of the auditory tubes can be examined. Farther down are the base of the tongue, the anterior surface of the epiglottis with the medial and lateral glosso-epiglottic folds bounding the valleculæ, and the pyriform sinuses. Beyond these is the entrance to the larynx, bounded on either side by the aryepiglottic folds,

in each of which are two rounded eminences corresponding to the corniculate and cuneiform cartilages. Within the larynx (fig. 1128) on either side are the ventricular and vocal folds (false and true vocal cords) with the ventricle of the larynx between them. Still deeper, the cricoid cartilage and the anterior parts of some of the cartilaginous rings of the trachea are visible, and sometimes, during deep inspiration, the bifurcation of the trachea.

FIG. 1129.—Front of left eye with eyelids separated to show structures at medial commissure.

THE EYE

The palpebral fissure is elliptical in shape, and varies in form and size in different individuals and in different races of mankind; normally it is oblique, in a direction upwards and lateralwards, so that the lateral commissure is on a slightly higher level than the medial. When the eyes are

directed forwards as in ordinary vision the superior part of the cornea is covered by the upper eyelid and its inferior margin is on a level with the free margin of the lower eyelid.

At the medial commissure (fig. 1129) are the *caruncula lacrimalis* and the *plica semilunaris*. When the lids are everted, the tarsal glands appear as a series of

FIG. 1130.—The interior of the posterior half of the left eyeball.

vertical parallel rows of light yellow granules. On the margins of the lids about 5 mm. from the medial commissure are the *puncta lacrimalia*; in the natural condition they are in contact with the conjunctiva of the bulb of the eye, so that it is necessary to evert the eyelids to expose them. The lacrimal sac lies immediately above and medially to a small tubercle which can be plainly felt on the inner part of the lower margin of the orbit. If the eyelids be drawn lateralwards a prominent cord, the medial palpebral ligament, can be felt beneath the tightened skin at the medial commissure; it crosses in front and a little above the middle of the lacrimal sac, and forms a useful guide to it. The direction of the nasolacrimal duct is indicated by a line from the lacrimal sac to the first upper molar tooth; the length of the duct is about 18 mm.

On looking into the eye, the iris with its opening, the pupil, and the front of the lens can be examined, but for investigation of the retina an ophthalmoscope is necessary. With this instrument the lens, the vessels of the retina, the optic disc, and the macula lutea can all be inspected (fig. 1130).

On the lateral surface of the nasal part of the frontal bone the pulley of the *Obliquus superior* can be easily reached by pushing the finger backwards along the roof of the orbit; the tendon of the muscle can be traced for a short distance backwards and lateralwards from the pulley.

THE EAR

The various prominences and fossæ of the auricula (pp. 978 to 981) are visible (fig. 1131). The orifice of the external acoustic meatus is exposed by drawing the tragus forwards; at the orifice are a few short crisp hairs which serve to prevent the entrance of dust or of small

FIG. 1131.—The auricula or pinna. Lateral surface.

insects; beyond this the secretion of the ceruminous glands serves to catch any small particles which may find their way into the meatus. The interior of the

FIG. 1132.—The right tympanic membrane, as seen through a speculum.

meatus can be examined through a speculum. At the junction of its bony and cartilaginous portions an obtuse angle is formed which projects into the antero-inferior wall and produces a narrowing of the lumen. The cartilaginous part, however, is connected to the bony part by fibrous tissue only, which renders the

FIG. 1133.—Left temporal bone showing surface markings for the tympanic antrum (red), transverse sinus (blue), and facial nerve (yellow).

outer portion of the meatus very movable, and therefore by drawing the auricula upwards, backwards, and slightly outwards, the canal is rendered almost straight.

In children the meatus is very short, and this should be remembered in introducing a speculum.

Through the speculum the greater part of the tympanic membrane (fig. 1132) is visible. It is a pearly-grey, slightly glistening membrane; in the adult it is placed obliquely so as to form with the floor and with the anterior wall of the meatus an angle of about fifty-five degrees; at birth it is more horizontal and situated in almost the same plane as the base of the skull. The membrane is concave outwards, and the point of deepest concavity is a little below the centre. Running upwards and slightly forwards from this point is a reddish-yellow streak produced by the manubrium of the malleus. This streak ends above near the roof of the meatus at a small white rounded prominence which is caused by the lateral process of the malleus projecting against the membrane. The anterior and posterior malleolar folds extend from the prominence to the circumference of the membrane and form the lower boundary of the pars flaccida of the membrane. Behind the streak caused by the manubrium of the malleus a shorter and fainter streak can sometimes be distinguished; this is the long crus of the incus. A narrow triangular patch extending downwards and forwards from the lower end of the manubrium mallei reflects the light more brightly than any other part, and is usually described as the cone of light.

Tympanic antrum.—The site of the tympanic antrum is indicated by the supra-meatal triangle (fig. 1133) which is bounded above by the posterior root of the zygomatic arch, behind by a vertical line from the posterior border of the bony external acoustic meatus, in front and below by the upper margin of the meatus.

THE NECK (fig 1134)

Muscles.—The posterior belly of the *Digastricus* is marked out by a line from the tip of the mastoid process to the junction of the greater cornu and body of the hyoid bone; a line from this latter point to one just laterally to the symphysis menti

FIG. 1134.—Side of neck, showing chief surface markings.

indicates the position of the anterior belly. The line of the *Omo-hyoideus* begins at the lower border of the body of the hyoid bone, runs downwards and lateralwards to cross the *Sterno-cleido-mastoideus* at the level of the cricoid cartilage, and then runs more horizontally to the acromial end of the clavicle.

Arteries.—The position of the *common carotid* artery in the neck is indicated by a line drawn from the upper part of the sternal end of the clavicle to a point midway between the tip of the mastoid process and the angle of the mandible.

From the clavicle to the upper border of the thyroid cartilage this line overlies the common carotid artery, beyond this it is over the external carotid artery. The external carotid artery may be otherwise marked out by the upper part of a line, arching slightly forwards, from the side of the cricoid cartilage to the front of the orifice of the external acoustic meatus.

The points of origin of the main branches of the external carotid artery are related to the tip of the greater cornu of the hyoid bone as follows: (1) the *superior thyroid*, just below it; (2) the *lingual*, on a level with it; (3) the *external maxillary* (facial) and (4) the *occipital*, a little above and behind it.

The *subclavian* artery is indicated on the surface by a curved line, convex upwards, from the sternoclavicular articulation to the middle of the clavicle. The highest point of the convexity is about 2 cm. above the clavicle.

Veins. The surface marking for the *internal jugular* vein is parallel with and slightly lateral to that for the common carotid artery. The position of the *external jugular* vein is marked by a line from the angle of the mandible to the middle of the clavicle. A point on this line about 4 cm. above the clavicle indicates the spot where the vein pierces the deep fascia. The line of the *anterior jugular* vein begins close to the symphysis menti, runs downwards parallel with and a little to one side of the middle line, and, at a short distance above the jugular notch, turns lateralwards to the external jugular.

Nerves. The *facial* nerve at its exit from the stylomastoid foramen is situated, in the adult, about 2.5 cm. from the surface, opposite the middle of the anterior border of the mastoid process; a horizontal line from this point to the ramus of the mandible overlies the stem of the nerve. In the infant there is no mastoid process, and the foramen is placed superficially just behind the meatus. To mark the course of the *accessory* nerve a line is drawn from a point midway between the angle of the mandible and the tip of the mastoid process to a point on the anterior border of the Sternocleidomastoideus 4 cm. below the apex of the mastoid process, or to the midpoint of the posterior border of the muscle; the line is continued across the posterior triangle of the neck to the Trapezius.

The cutaneous branches of the cervical plexus emerge from beneath the posterior border of the Sternocleidomastoideus and may be indicated as follows: the *lesser occipital* appears just above the midpoint of the border and ascends along it to the scalp; the *great auricular* and *cervical cutaneous* start from the middle of the border, the former running upwards towards the lobule of the auricle, the latter crossing the Sternocleidomastoideus at right angles to its long axis; the *supraclavicular* nerves emerge just below the middle of the posterior border and run down over the clavicle. The *phrenic* nerve begins at the level of the middle of the thyroid cartilage and runs behind the clavicle about midway between the anterior and posterior borders of the Sternocleidomastoideus.

The upper border of the *brachial plexus* is indicated by a line from the side of the cricoid cartilage to the middle of the clavicle.

SURFACE ANATOMY OF THE BACK

Bones.—The only subcutaneous parts of the vertebral column are the apices of the spinous processes. These are distinguishable at the bottom of a furrow which runs down the middle line of the back from the external occipital protuberance to the middle of the sacrum. In the *cervical region* the furrow is broad and ends below in a conspicuous projection caused by the spinous processes of the seventh cervical and first thoracic vertebrae. Above this, the spinous process of the sixth cervical vertebra sometimes forms a projection; the other cervical spinous processes are sunken, but that of the epistropheus can be felt. In the *thoracic region* the furrow is shallow and during stooping disappears, and then the spinous processes become more or less visible; the markings produced by them are small and close together. In the *lumbar region* the furrow is deep and the situations of the spinous processes are frequently indicated by little pits, especially when the muscles in the loins are well developed. In the *sacral region* the furrow is shallow and flattened, and ends below at the most prominent part of the dorsal surface of the sacrum, i.e. the spinous process of the third sacral vertebra. At the bottom of the sacral furrow the irregular dorsal surface of the sacrum may be felt, and below this, in the deep groove running to the anus, the coccyx.

Muscles.—The deep muscles of the back are so covered by those of the upper extremity (fig. 1135) that they have very little influence on surface form. The *Splenii* by their divergence serve to broaden out the upper part of the back of the

FIG. 1135.—Surface anatomy of the back.

neck and produce a fulness in this situation. In the loin the *Sacrospinales*, bound down by the lumbodorsal fascia, form rounded vertical eminences which determine the depth of the spinal furrow and taper below to a point on the dorsal surface of the sacrum. The continuations of the *Sacrospinales* in the lower thoracic region form flattened planes which are gradually lost on passing upwards.

SURFACE MARKINGS OF THE BACK

Bony landmarks.—In order to identify any particular spinous process it is customary to count from the prominence caused by the seventh cervical and first thoracic; of these the latter is the more prominent, although the seventh cervical is known as the *vertebra prominens*. The root of the spine of the scapula is on

FIG. 1136.—Diagram showing the relation of the medulla spinalis to the dorsal surface of the trunk. The bones are outlined in red.

a level with the tip of the spinous process of the third thoracic vertebra, and the inferior angle with that of the seventh.

The highest point of the iliac crest is on a level with the spinous process of the fourth lumbar vertebra, and the posterior superior iliac spine with that of the second sacral vertebra.

Medulla spinalis.—The position of the lower end of the medulla spinalis varies slightly with the movements of the vertebral column, but, in the adult, in the upright posture it is usually at the level of the spinous process of the second lumbar vertebra (fig. 1136); at birth it is at the level of the fourth.

The *subdural* and *subarachnoid cavities* end below opposite the spinous process of the third sacral vertebra (fig. 1137).

FIG. 1138.—Scheme showing the relations of the regions of attachment of the spinal nerves to the vertebral spinous processes. (After Reid.)

SURFACE ANATOMY OF THE THORAX

Bones.—The skeleton of the thorax is covered to a considerable extent by muscles, so that in the strongly developed muscular subject it is for the most part concealed. In thin persons the ribs, especially in the lower and lateral regions, stand out as prominent ridges with the sunken intercostal spaces between them.

In the middle line, in front, the anterior surface of the *sternum* can be felt throughout its entire length at the bottom of the sternal furrow, between the *Pectorales majores*. These muscles overlap the anterior surface somewhat, so

that the whole width of the sternum is not subcutaneous, and this overlapping is greatest opposite the middle of the bone; the furrow, therefore, is wide at its upper and lower parts but narrow in the middle. At the upper border of the manubrium sterni is the *jugular notch*: the lateral parts of this notch are obscured by the tendinous origins of the *Sternocleidomastoidei*, which appear as oblique cords narrowing and deepening the notch. At the junction of the manubrium and body is a well-defined transverse ridge, the *sternal angle* (*angulus Ludovici*). From the middle of the sternum the sternal furrow widens and ends at the junction of the body of the sternum with the xiphoid process. Immediately below this

FIG. 1139.—The left side of the thorax.

is the *infrasternal notch*; between the sternal ends of the seventh costal cartilages, and below the notch, is a triangular depression, the *epigastric fossa*, in which the *xiphoid process* can be felt.

On either side of the sternum the costal cartilages and ribs on the front of the thorax are partially obscured by the *Pectoralis major*, through which, however, they can be felt as ridges with yielding intervals between them corresponding to the intercostal spaces. The second space is the widest, the third and fourth are somewhat narrower, and the others, with the exception of the last two, are comparatively narrow.

Below the lower border of the *Pectoralis major* on the front of the chest, the broad flat outlines of the ribs, and the more rounded outlines of the costal cartilages, are often visible. The lower boundary of the front of the thorax is most plainly seen when the body is bent backwards; it is formed by the xiphoid process, the cartilages of the seventh, eighth, ninth, and tenth ribs, and the ends of the cartilages of the eleventh and twelfth ribs.

On either side of the thorax, from the axilla downwards, the external surfaces of the ribs may be defined. Although covered by muscles, all the ribs, with the exception of the first, can generally be followed without difficulty over the front

and sides of the thorax. The first rib, being almost completely covered by the clavicle, can only be distinguished in a small portion of its extent.

At the back, the angles of the ribs lie on slightly marked oblique lines some distance from the spinous processes of the vertebræ. The lines diverge somewhat as they descend, and laterally to each is a broad convex surface caused by the projection of the ribs beyond their angles. Over this surface, except where covered by the scapula, the individual ribs can be distinguished.

Muscles.—The surface muscles covering the thorax belong to the musculature of the upper extremity (figs. 1139, 1143), and will be described in that section

FIG. 1140.—Front of thorax, showing surface relations of bones, lungs (purple), pleuræ (blue), and heart (red outline).

(p. 1247). There is, however, an area of practical importance bounded by these muscles. It is limited above by the lower border of the Trapezius, below by the upper border of the Latissimus dorsi, and laterally by the vertebral border of the scapula; the floor is partly formed by the Rhomboideus major. If the scapulae be drawn forwards by folding the arms across the chest, and the trunk bent forwards, parts of the sixth and seventh ribs and the interspace between them become subcutaneous and available for auscultation. The space is therefore known as the *triangle of auscultation*.

Mamma.—The size of the mamma is subject to great variations. In the adult nulliparous female it extends vertically from the second to the sixth rib, and transversely from the side of the sternum to the midaxillary line. In the male and in the nulliparous female the *mammary papilla* or *nipple* is situated in the fourth interspace about 9 or 10 cm. from the middle line.

SURFACE MARKINGS OF THE THORAX

Bony landmarks.—The second costal cartilage corresponds to the sternal angle, and is so readily found that it is used as a starting-point from which to count the ribs. The lower border of the Pectoralis major at its origin corresponds to the

fifth rib; the uppermost visible digitation of the *Serratus anterior* indicates the sixth rib.

The jugular notch is at the level of the lower border of the body of the second thoracic vertebra, and the sternal angle at the level of the fibrocartilage between the fourth and fifth; the junction between the body and xiphoid process of the sternum corresponds to the fibrocartilage between the ninth and tenth thoracic vertebra.

The degree of obliquity of the ribs is such that 'if a horizontal line be drawn round the body at the level of the inferior angle of the scapula, while the arms

FIG. 1141.—Side of thorax, showing surface markings for bones, lung (purple), pleura (blue), and spleen (green).

are at the sides, the line would cut the sternum in front between the fourth and fifth ribs, the fifth rib in the nipple line and the ninth rib at the vertebral column.' (Treves.)

Diaphragm.—The shape and variations of the Diaphragm as seen by skiagraphy have already been described (p. 455)

Surface lines.—For clinical purposes, and for convenience of description, the surface of the thorax has been mapped out by arbitrary lines (fig. 1144). On the front of the thorax the most important vertical lines are the *midsternal* or middle line, and the *mammary* which descends vertically from a point midway between the centre of the jugular notch and the tip of the acromion, and, if prolonged, almost corresponds with the lateral line on the front of the abdomen. Other vertical lines are the *lateral sternal* along the sternal margin, and the *parasternal* midway between the latter and the mammary line (fig. 1144).

On either side of the thorax the *anterior* and *posterior axillary* lines are drawn vertically from the corresponding axillary folds; the *midaxillary* line runs downwards from the apex of the axilla.

On the posterior surface of the thorax the *scapular* line is drawn vertically through the inferior angle of the scapula.

Pleuræ (figs. 1140, 1141).—The lines of reflection of the pleuræ can be indicated on the surface. On the *right* side the line passes through the sternoclavicular

articulation and runs downwards and medialwards to the midpoint of the junction between the manubrium and body of the sternum. It follows the midsternal line to the lower end of the body of the sternum or on to the xiphoid process, and then turns lateralwards and downwards across the seventh sternocostal articulation. It crosses the eighth costochondral junction in the mammary line, the tenth rib in the midaxillary line, and is prolonged thence to the spinous process of the twelfth thoracic vertebra, to reach which it passes below the level of the medial part of the twelfth rib. The most dependent part of the pleural cavity is opposite the tenth rib in the midaxillary line.

On the *left* side the line passes through the sternoclavicular articulation, reaches the midpoint of the junction between the manubrium and body of the sternum, and extends down the midsternal line to the level of the fourth costal cartilage. It then inclines to the left and is continued downwards slightly laterally to the sternal border, as far as the sixth costal cartilage. Running downwards and lateralwards from this point it crosses the seventh costal cartilage, and from this onwards it is similar to the line on the right side but at a slightly lower level.

Lungs (figs. 1140, 1141).—The *apex* of the lung is situated in the neck above the medial third of the clavicle. The average height to which it rises above the clavicle is about 2.5 cm.

In order to mark out the *anterior borders* of the lungs two lines, one from each apex, are drawn downwards and medialwards across the sternoclavicular articulation and manubrium sterni until they meet, or almost meet, at the midpoint of the junction between the manubrium and body of the sternum. From this point the two lines run downwards, in the midsternal line, as far as the level of the fourth costal cartilages. On the *right* side the line is continued in the midsternal line to the level of the sixth costal cartilage, and then it turns lateralwards and downwards. On the *left* side the line curves lateralwards and downwards across the fourth sternocostal articulation to reach the parasternal line at the fifth costal cartilage, and then turns medialwards and downwards to the sixth sternocostal articulation.

In the position of expiration the *lower border* of the lung may be marked by a slightly curved line with its convexity downwards, from the sixth sternocostal junction to the tenth thoracic spinous process. This line crosses the mammary line at the sixth, the midaxillary line at the eighth, and the scapular line at the tenth rib.

The *posterior borders* of the lungs are indicated by lines drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the vertebral column, across the costovertebral joints, as low as the spinous process of the tenth thoracic vertebra.

The position of the *oblique fissure* in either lung can be shown by a line drawn from the spinous process of the second thoracic vertebra round the side of the thorax to the sixth rib in the mammary line; this line corresponds roughly to that of the vertebral border of the scapula when the hand is placed on the top of the head. The *horizontal fissure* in the right lung is indicated by a line drawn from the midpoint of the preceding, or from the point where it cuts the midaxillary line, to the midsternal line at the level of the fourth costal cartilage.

The *roots* of the lungs are placed opposite to the spinous processes of the fourth, fifth and sixth thoracic vertebrae.

Trachea.—This may be marked out on the back by a line from the spinous process of the sixth cervical to that of the fourth thoracic vertebra, where it bifurcates; from its bifurcation the two bronchi are directed downwards and lateralwards. Anteriorly, the point of bifurcation is opposite to or a little below the sternal angle.

Œsophagus.—The extent of the œsophagus may be indicated on the back by a line from the sixth cervical spinous process to a point 2.5 cm. on the left of the ninth thoracic spinous process.

Heart.—The outline of the heart in relation to the front of the thorax (figs. 1140, 1142) can be represented by a quadrangular figure. (a) The apex of the heart is first determined as a point in the fifth interspace, 9 cm. to the left of the midsternal line. The other three points are: (b) the seventh right sternocostal articulation; (c) the upper border of the third right costal cartilage 1 cm. from the right lateral sternal line; (d) the lower border of the second left costal

cartilage 2.5 cm. from the left lateral sternal line. A line joining (a) to (b) and traversing the junction of the body of the sternum with the xiphoid process represents the lower border of the heart. The right and left borders are represented respectively by lines joining (c) and (a) to (c); both lines are convex lateralwards, but the convexity is more marked on the right, where its summit is 4 cm. distant from the midsternal line of the fourth costal cartilage.

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder is overlapped by lung and gives a more or less resonant note. The former is known as the area of superficial cardiac dullness, the latter as the area of deep cardiac dullness. The area

FIG. 1142.—Diagram showing relative position of heart to front of thoracic wall.

Ant. Anterior segment of tricuspid valve. A.O. Aorta. A.P. Anterior papillary muscle. In. Innominate artery. L.C.C. Left common carotid artery. L.S. Left subclavian artery. L.V. Left ventricle. P.A. Pulmonary artery. R.A. Right atrium. R.V. Right ventricle. V.S. Ventricular septum.

of superficial cardiac dullness is somewhat triangular; from the apex of the heart two lines are drawn to the midsternal line, one to the level of the fourth costal cartilage, the other to the junction between the body and xiphoid process of the sternum; the portion of the midsternal line between these points is the base of the triangle. Latham lays down the following rule as a sufficient practical guide for the definition of the area of superficial dullness: 'Make a circle of two inches in diameter round a point midway between the nipple and the end of the sternum.'

The *coronary sulcus* (auriculoventricular groove) can be indicated by a line from the third left, to the sixth right, sternocostal joint. The *anterior longitudinal sulcus* is a finger's-breadth to the right of the left margin of the heart and parallel with it.

The positions of the orifices of the heart are as follows: The *pulmonary orifice* is situated in the upper angle of the third left sternocostal articulation; the *aortic* is a little below and medial to this, close to the articulation. The *left atrioventricular* orifice is opposite the fourth costal cartilage, and rather to the left of the midsternal line; the *right atrioventricular* is a little lower, opposite the fourth interspace

of the right side. The lines indicating the atrioventricular orifices are parallel with and slightly below the line of the coronary sulcus.

Arteries.—The line of the *ascending aorta* begins slightly to the left of the mid-sternal line opposite the third costal cartilage, and extends upwards and to the right to the level of the upper border of the second right costal cartilage. The *aortic arch* lies behind the lower half of the manubrium sterni. A line from the middle of the manubrium sterni to the right sternoclavicular articulation represents the site of the *innominate artery*, while another line from a point slightly to the left of the middle of the manubrium sterni to the left sternoclavicular articulation indicates the position of the thoracic part of the *left common carotid artery*.

The *internal mammary artery* descends behind the first six costal cartilages about 1 cm. from the lateral sternal line.

Veins.—The line of the *right innominate vein* crosses the right sternoclavicular joint and the upper border of the first right costal cartilage about 1 cm. from the lateral sternal line; that of the *left innominate vein* extends from the left sternoclavicular articulation to meet the right at the upper border of the first right costal cartilage. The junction of the two lines indicates the origin of the *superior vena cava*, and the line of this vessel is continued vertically down to the level of the third right costal cartilage. The *inferior vena cava* opens into the right atrium at the level of the upper margin of the sixth right costal cartilage about 2 cm. from the midsternal line.

SURFACE ANATOMY OF THE ABDOMEN

Skin.—The skin of the front of the abdomen is thin. In the male it is often thickly clad with hairs, especially towards the lower part of the middle line; in the female the hairs are confined to the pubes. Just below the iliac crest is a shallow groove termed the *iliac furrow*, while in the site of the inguinal ligament a sharper fold known as the *fold of the groin* is easily distinguishable.

After distension of the abdomen from pregnancy or other causes the skin commonly presents transverse white lines which are quite smooth, being destitute of papillae; these are known as *striae gravidarum* or *striae albae*. The *linea nigra* of pregnancy is often seen as a brown streak in the middle line between the umbilicus and symphysis pubis.

In the middle line of the front of the abdomen is a shallow furrow which extends from the junction between the body of the sternum and the xiphoid process to a short distance below the umbilicus; it corresponds to the *linea alba*. The umbilicus is situated in the middle line, but varies as regards its height; in an adult subject it is always placed above the middle point of the body, and is slightly below the level of the highest points of the iliac crests.

Bones.—The bones in relation with the surface of the abdomen are (1) the lower part of the vertebral column and the lower ribs and (2) the pelvis; the former have already been described (pp. 1226 and 1229), the latter will be considered with the lower limb.

Muscles (fig. 1143).—The only muscles of the abdomen which have any considerable influence on surface form are the *Obliquus externus abdominis* and the *Rectus abdominis*. The upper digitations of origin of the *Obliquus externus* are well marked and interdigitate with those of the *Serratus anterior*; the lower are covered by the border of the *Latissimus dorsi*. The attachment of the *Obliquus externus* and *Obliquus internus* to the iliac crest forms a thick oblique roll which terminates the iliac furrow. On the front of the lateral region of the abdomen an undulating line sometimes marks the passing of the muscular fibres of the *Obliquus externus* into its aponeurosis. The posterior margin of the *Obliquus externus* is frequently separated from the lateral margin of the *Latissimus dorsi* by a small angular interval—the *lumbar triangle*—the base of which is formed by the iliac crest, and the floor by the *Obliquus internus*.

The lateral margin of the *Rectus abdominis* is indicated by the *linea semilunaris*, which is easily defined when the muscle is in action. On the surface of the *Rectus* three transverse furrows, the *tendinous inscriptions*: the upper two of these, one opposite, or a little below, the tip of the xiphoid process, and the other midway between this point and the umbilicus, are usually well marked; the third, opposite the umbilicus, is not so distinct. Between the two *Recti* the furrow of

the linea alba can be traced from the xiphoid process to a point just below the umbilicus, beyond which it disappears owing to the apposition of the muscles.

Vessels.—In thin subjects the pulsation of the *abdominal aorta* is felt on making deep pressure in the middle line above the umbilicus.

FIG. 1143.—Surface anatomy of the front of the thorax and abdomen.

Viscera.—Under normal conditions the various portions of the *digestive tube* cannot be identified by simple palpation, but under certain conditions peristalsis of the coils of small intestine can be observed in persons with extremely thin abdominal walls. In cases of constipation it is commonly possible to trace portions of the great intestine by feeling the faecal masses within the gut. In thin persons with relaxed abdominal walls the iliac portion of the descending colon can be felt

in the left iliac region—rolling under the fingers when empty and forming a distinct tumour when distended.

The *liver* lies mainly under cover of the lower ribs and their cartilages, but in the epigastric fossa a portion of it comes in contact with the abdominal wall. The position of the liver varies according to the posture of the body. In the erect posture the inferior margin of the liver projects about 1 cm. below the lower margin of the right costal cartilages, and can often be felt if the abdominal wall is thin. In the supine position the liver recedes above the lower margin of the thorax and cannot then be detected by the fingers; in the prone position it falls forwards and is then generally palpable in a patient with lax abdominal walls. Its position varies with the respiratory movements: during a deep inspiration it descends below the ribs, in expiration it is raised. Pressure from without, as in tight lacing, displaces the liver considerably, its anterior edge frequently extending as low as the iliac crest. Again, the position of the liver varies greatly with the state of the stomach and intestines; when these are empty the liver descends, when they are distended it is pushed upwards.

The *pancreas* can sometimes be felt in emaciated subjects, if the stomach and colon are empty, by making deep pressure in the middle line about 7 or 8 cm. above the umbilicus.

The *kidneys* are deeply situated at the back of the abdominal cavity, and cannot be palpated unless enlarged or misplaced.

SURFACE MARKINGS OF THE ABDOMEN

Bony landmarks.—Above, the chief bony markings are the xiphoid process, the lower six costal cartilages and the anterior ends of the lower six ribs. The junction between the body of the sternum and the xiphoid process is at the level of the tenth thoracic vertebra. Below, the main landmarks are the symphysis pubis and the pubic crest and tubercle, the anterior superior iliac spine, and the iliac crest.

Muscles (fig. 1143).—The *Rectus abdominis* lies between the linea alba and the linea semilunaris; the latter is indicated by a curved line, convex lateralwards, from the tip of the cartilage of the ninth rib to the pubic tubercle; at the level of the umbilicus the linea semilunaris is about 7 cm. from the middle line. The line indicating the junction of the muscular fibres of *Obliquus externus* with its aponeurosis extends from the tip of the ninth costal cartilage to a point just medially to the anterior superior iliac spine.

The *umbilicus* is at the level of the fibrocartilage between the third and fourth lumbar vertebrae.

The *subcutaneous inguinal ring* is situated 1 cm. above and lateral to the pubic tubercle; the *abdominal inguinal ring* is about 1 cm. above the middle of the inguinal ligament. The position of the *inguinal canal* is indicated by a line joining these two points.

Surface lines.—For convenience of description of the viscera and of reference to morbid conditions of the contained parts, the abdomen is divided into nine regions, by imaginary planes, two horizontal and two sagittal, the edges of the planes being indicated by lines drawn on the surface of the body (fig. 1144). In the older method the upper, or subcostal, horizontal line encircles the body at the level of the lowest points of the tenth costal cartilages; the lower, or inter-tubercular, is a line carried through the highest points of the iliac crests seen from the front, i.e. through the tubercles on the iliac crests about 5 cm. behind the anterior superior spines. An alternative method is that of Addison, who adopts the following lines: (1) an upper transverse, the *transpyloric*, halfway between the jugular notch and the upper border of the symphysis pubis; this indicates the edge of the transpyloric plane which in most cases cuts through the pylorus, the tips of the ninth costal cartilages and the lower border of the first lumbar vertebra; (2) a lower transverse line midway between the transpyloric and the upper border of the symphysis pubis; this is termed the *trans-tubercular* since it very nearly corresponds to that passing through the tubercles on the iliac crests; behind, its plane cuts the body of the fifth lumbar vertebra.

By means of these horizontal planes the abdomen is divided into three zones named from above, subcostal, umbilical, and hypogastric. Each of these is further

subdivided into three regions by the two sagittal planes, which are indicated on the surface by a right and a left lateral line drawn vertically through points halfway between the anterior superior iliac spine and the middle line. The middle region of the upper zone is called the epigastric, and the lateral regions the right and left hypochondriac. The central region of the middle zone is the umbilical, and the lateral regions the right and left lumbar. The middle region

FIG. 1144.—Surface lines of the front of the thorax and abdomen.

of the lower zone is the hypogastric or pubic, and the lateral regions are the right and left iliac or inguinal. The epigastric, umbilical, and pubic regions can each be divided into right and left portions by the middle line. In the following description of the viscera the regions marked out by Addison's lines are those referred to.

Stomach (fig. 1146).—The shape of the stomach is constantly undergoing alteration; it is affected by the particular phase of the process of gastric digestion, by the state of the surrounding viscera, and by the amount and character of its contents. Its position also varies with that of the body (fig. 1145), so that it is impossible to indicate it on the surface with any degree of accuracy. The measurements given refer to a moderately filled stomach with the body in the supine position.

The cardiac orifice is opposite the seventh left costal cartilage, about 2.5 cm. from the side of the sternum; it corresponds to the level of the tenth thoracic vertebra. The pyloric orifice is on the transpyloric line about 1 cm. to the right of the middle line, or alternatively 5 cm. below the seventh right sternocostal articulation; it is at the level of the first lumbar vertebra. A curved line, convex downwards and to the left, joining these points indicates the lesser curvature. In the left lateral line the fundus of the stomach reaches as high as the fifth intercostal space or the sixth costal cartilage, a little below the apex of the heart. To indicate the greater curvature a curved line is drawn from the cardiac orifice to the summit of the fundus, thence downwards and to the left, finally turning medialwards to the pyloric orifice, but passing, on its way, through the intersection of the left lateral with the transpyloric line. The portion of the stomach which is in contact with the abdominal wall can be represented roughly by a triangular area, the base of which is formed by a line drawn from the tip of the tenth left costal cartilage to the tip of the ninth right cartilage, and the sides by two lines drawn from the end of the eighth left costal cartilage to the ends of the base line.

A space of some clinical importance—the *space of Traube*—overlies the stomach and may be thus indicated. It is semilunar in outline and has the following

FIG. 1145.—Skiagrams of a moderately distended stomach, showing the influence of posture. (Modified from Hertz.)

A. With the patient in the erect posture. B. With the patient lying down.

boundaries: the lower edge of the left lung, the anterior border of the spleen, the left costal margin, and the inferior margin of the left lobe of the liver.

Duodenum (fig. 1147).—The superior part is nearly horizontal and extends from the pylorus to the right lateral line; the descending part is situated medially to the right lateral line, from the transpyloric line to a point midway between the transpyloric and transtuberular lines. The horizontal part runs with a slight upward slope from the end of the descending part to the left of the middle line; the ascending part is vertical, and ends in the duodenojejunal flexure, about 2.5 cm. to the left of the middle line and a little below the transpyloric plane.

Small intestine.—The coils of small intestine occupy the front of the abdomen. For the most part those of the jejunum are situated on the left side, i.e. in the left lumbar and iliac regions, and in the left half of the umbilical region. Those of the ileum lie towards the right in the right lumbar and iliac regions, in the right half of the umbilical region, and in the hypogastric region; a portion of the ileum is within the pelvis. The end of the ileum, i.e. the *ileocolic junction*, is slightly below and medial to the intersection of the right lateral and transtuberular lines.

Cæcum and vermiform process.—The cæcum is in the right iliac and hypogastric regions; its position varies with its degree of distension, but the midpoint of a line drawn from the right anterior superior iliac spine, to the upper margin of the symphysis pubis will mark approximately the middle of its lower border.

The position of the opening of the *vermiform process* into the cæcum is indicated by a point on the lateral line on a level with the anterior superior iliac spine.

Ascending colon.—The ascending colon passes upwards through the right lumbar region, just laterally to the right lateral line. The *right colic flexure* is situated in the right lower angle of intersection of the transpyloric and right lateral lines.

Transverse colon.—The transverse colon crosses the abdomen on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach.

Descending colon.—The *left colic flexure* is situated in the upper left angle of the intersection between the left lateral and transpyloric lines. The descending colon courses down through the left lumbar region, laterally to the left lateral line, thence slightly medialwards to the left lateral line at the level of the anterior superior iliac spine.

Liver (fig. 1146).—The upper limit of the right lobe of the liver, in the middle line, is at the level of the junction between the body and xiphoid process of the

FIG. 1146.—Front of abdomen, showing surface markings for liver, stomach, and great intestine.

sternum ; on the right side the line must be carried upwards as far as the fifth costal cartilage in the mammary line, and then downwards to reach the seventh rib at the side of the thorax. The upper limit of the left lobe can be defined by continuing this line to the sixth left costal cartilage, 5 cm. from the middle line. The lower limit is represented by a line drawn 1 cm. below the lower margin of the thorax on the right side as far as the ninth costal cartilage, thence obliquely upwards to the eighth left costal cartilage, crossing the middle line at the transpyloric plane and finally, with a slight left convexity, to the end of the line indicating the upper limit.

According to Birmingham, the limits of the normal liver may be marked out on the surface of the body in the following manner. Take three points : (a) 1.25 cm. below the right nipple ; (b) 1.25 cm. below the tip of the right tenth rib ; (c) 2.5 cm. below the left nipple. Join (a) and (c) by a line slightly concave upwards at its middle part ; (a) and (b) by a line slightly convex lateralwards ; and (b) and (c) by a line slightly convex downwards.

The fundus of the *gall-bladder* approaches the surface behind the anterior end of the ninth right costal cartilage close to the lateral margin of the *Rectus abdominis*.

FIG. 1147.—Front of abdomen, showing surface markings for duodenum, pancreas and kidneys.

A A'. Plane through joint between body and xiphoid process of sternum. B B'. Plane midway between A A' and transpyloric plane. C C'. Plane midway between transpyloric and transtubercular planes.

Pancreas (fig. 1147).—The pancreas lies in front of the second lumbar vertebra. Its head occupies the curve of the duodenum, and is therefore indicated by the same lines as that viscus; its neck corresponds to the pylorus. Its body extends along the transpyloric line, the bulk of it lying above this line, to the tail, which is in the left hypochondriac region slightly to the left of the lateral line and above the transpyloric line.

Spleen (figs. 1141, 1148).—To map out the spleen the tenth rib is taken as representing its long axis; vertically it extends from the upper border of the ninth rib to the lower border of the eleventh rib. The highest point is 4 cm. from the middle line of the back at the level of the tip of the ninth thoracic spinous process; the lowest and foremost point is in the midaxillary line at the level of the first lumbar spinous process.

Kidneys (figs. 1147, 1148).—The right kidney usually lies about 1 cm. lower than the left, but for practical purposes similar surface markings are taken for each.

On the front of the abdomen the upper pole lies midway between the plane of the lower end of the body of the sternum and the transpyloric plane, 5 cm. from

FIG. 1148.—Back of lumbar region, showing surface markings for kidneys, ureters, and spleen.

The lower portions of the lung and pleura are shown on the right side.

the middle line. The lower pole is situated midway between the transpyloric and transtuberular planes, 7 cm. from the middle line. The hilum is on the transpyloric plane, 5 cm. from the middle line.* Round these three points a kidney-shaped figure 4 cm. to 5 cm. broad is drawn two-thirds of which lie medially to the lateral line. To indicate the position of the kidney from the back, the parallelogram of Morris is used; two vertical lines are drawn, the first 2.5 cm., the second 9.5 cm. from the middle line; the parallelogram is completed by two horizontal lines, one drawn at the level of the tip of the spinous process of the eleventh thoracic vertebra, and the other at the level of the lower border of the spinous process of the third lumbar vertebra. The hilum is 5 cm. from the middle line at the level of the spinous process of the first lumbar vertebra.

Ureters.—On the front of the abdomen, the line of the ureter is from the hilum of the kidney to the pubic tubercle; on the back, from the hilum vertically downwards, passing through the posterior superior iliac spine (fig. 1148).

FIG. 1149.—Front of abdomen, showing surface markings for arteries and inguinal canal. The line A, A' is drawn at the level of the highest points of the iliac crests.

Vessels (fig. 1149).—The position of the *inferior epigastric artery* is marked by a line from a point midway between the anterior superior iliac spine and the pubic symphysis to the umbilicus. This line also indicates the lateral boundary of *Hesselbach's triangle*, the other boundaries of which are the lateral edge of *Rectus abdominis*, and the medial half of the inguinal ligament. The line of the *abdominal aorta* begins in the middle line about 4 cm. above the transpyloric line and ends at a point 2 cm. below and to the left of the umbilicus—or 2 cm. to the left of the middle line at the level of the highest points of the iliac crests (AA', fig. 1149); the abdominal aorta ends at the level of the fourth lumbar vertebra. A line drawn from the point of termination of the abdominal aorta to a point midway between the anterior superior iliac spine and the symphysis pubis overlies the common and external iliac arteries. The *common iliac* is represented by the upper one-third, and the *external iliac* by the lower two-thirds of this line.

Of the larger branches of the abdominal aorta, the *celiac artery* is 4 cm., and the *superior mesenteric* 2 cm. above the transpyloric line; the *renal arteries* are 2 cm.

* Addison says (1) that one-third of the right kidney and two-fifths of the left are above the transpyloric plane, and (2) that one-third of the right kidney and two-fifths of the left lie on the medial side of the corresponding lateral line.

below this line. The *inferior mesenteric artery* is 4 cm. above the bifurcation of the abdominal aorta.

Nerves.—The courses of the lower six thoracic nerves on the anterior abdominal wall are represented by lines continuing those of the ribs. The seventh thoracic nerve ends at the level of the xiphoid process, the tenth at the level of the umbilicus, and the twelfth about midway between the umbilicus and the upper border of the symphysis pubis. The anterior branch of the iliohypogastric nerve becomes cutaneous about 3 cm. above the subcutaneous inguinal ring; the ilio-inguinal nerve at the ring.

SURFACE ANATOMY OF THE PERINÆUM

• **Skin.**—In the middle line of the posterior part of the perinæum and about 4 cm. in front of the tip of the coccyx is the anal orifice, the skin around which is thrown into a series of folds which converge towards the orifice, and are continued

FIG. 1150.—Median sagittal section of male pelvis.

upwards into the lower part of the anal canal. The junction of the mucous membrane of the anal canal with the skin is marked by a white line which indicates also the line of contact of the external and internal Sphincters. The external genital organs are situated in the anterior part of the perinæum. The skin covering the scrotum is rough and corrugated, but over the penis it is smooth. Extending forwards from the anus on to the scrotum and penis is a median ridge which indicates the scrotal raphe. In the *female* are seen the skin reduplications forming the labia majora and minora laterally, the prepuce of the clitoris in front, and still more anteriorly the mons pubis (fig. 1151).

Bones.—In the anterolateral boundaries of the perinæum, the whole outline of the pubic arch can be readily traced ending in the ischial tuberosities. Behind in the middle line is the tip of the coccyx.

Muscles and ligaments.—The margin of the *Gluteus maximus* forms the posterolateral boundary of the perineum, and by pressing deeply the sacrotuberous ligament can be felt through the muscle. The only other muscles influencing surface form are the *Ischiocavernosus* covering the crus penis, which lies on the side of the pubic arch, and the *Sphincter ani externus*, which, in action, closes the anal orifice and causes a puckering of the skin around it.

SURFACE MARKINGS OF THE PERINEUM

A line drawn transversely in front of the ischial tuberosities divides the perineum into a posterior or rectal, and an anterior or urogenital, triangle. This line passes through the central point of the perineum, which is situated about 2.5 cm. in front of the anal aperture, or, in the male, midway between the anus and the reflection of the skin on to the scrotum.

FIG. 1151.—External genital organs of female. The labia minora have been drawn apart.

Rectum and Anal canal.—A finger inserted through the anal orifice is grasped by the *Sphincter ani externus*, passes into the region of the *Sphincter ani internus*, and higher up encounters the resistance of the *Puborectalis*; beyond this it may reach the lowest of the transverse rectal folds. In front (fig. 1150), the urethral bulb and membranous part of the urethra are first identified, and then about 4 cm. above the anal orifice the prostate is felt; beyond this the *vesiculæ seminales*, if enlarged, and the fundus of the bladder, when distended, can be recognised. On either side is the ischio-rectal fossa. Behind are the *anococcygeal body*, the pelvic surfaces of the coccyx and lower part of the sacrum, and the *sacrospinous ligaments*.

In the female the posterior wall and fornix of the vagina, and the cervix and body of the uterus can be felt in front, while somewhat laterally the ovaries can just be reached.

Male urogenital organs.—The corpora cavernosa penis can be followed backwards to the crura which are attached to the sides of the pubic arch. The glans penis, covered by the prepuce, and the external urethral orifice can be examined, and the course of the urethra traced along the under surface of the penis to the urethral bulb which is situated immediately in front of the central point of the perinæum. The testes can be palpated through the wall of the scrotum, and along the posterior border of each the curved epididymis can be felt; the spermatic cord ascends on the medial side of the epididymis, and may be traced upwards to the subcutaneous inguinal ring. The ductus deferens feels like a piece of whipcord, and thus can be easily recognized in the posterior part of the spermatic cord.

FIG. 1152.—Median sagittal section of female pelvis.

By means of a sound the general topography of the urethra and bladder can be investigated; with the urethroscope the interior of the urethra can be illuminated and viewed directly; with the cystoscope the interior of the bladder is in a similar manner illuminated for visual examination. In the bladder the main points to which attention is directed are: the trigone, the torus uretericus, the plicæ uretericæ, and the openings of the ureters and urethra (see fig. 1075).

Female urogenital organs.—In the pudendal cleft (fig. 1151) between the labia minora are the openings of the vagina and urethra. In the virgin the vaginal opening is partly closed by the hymen—after coitus the remains of the hymen are represented by the caruncula hymenales. Between the vaginal orifice and the frenulum of the labia is the fossa navicularis, while in the groove between the hymen and the labium minus, on either side, the small opening of the greater vestibular (Bartholin's) gland is visible. These glands when enlarged can be felt on either side of the posterior part of the vaginal orifice. By inserting a finger into the vagina the following structures may be examined through its wall (fig. 1152). Behind, from below upwards, are the anal canal, the rectum, and the recto-uterine

excavation. Projecting into the roof of the vagina is the vaginal portion of the cervix uteri with the external uterine orifice; in front of and behind the cervix are the anterior and posterior vaginal fornices. With a finger in the vagina and the other hand on the abdominal wall the whole of the cervix and body of the uterus, the uterine tubes, and the ovaries can be palpated. If a speculum be introduced into the vagina, the walls of the passage, the vaginal portion of the cervix, and the external uterine orifice can all be exposed for visual examination.

The external urethral orifice lies in front of the vaginal opening, and has rather prominent margins. The urethral canal in the female is very dilatable and can be explored with the finger. About 2.5 cm. in front of the external orifice of the urethra are the glans and prepuce of the clitoris, and still further forward, the mons pubis.

SURFACE ANATOMY OF THE UPPER EXTREMITY

Skin.—The skin covering the shoulder and arm is smooth and very movable on the underlying structures. In the axilla there are numerous hairs and many sudoriferous and sebaceous glands. On the medial side and front of the forearm the skin is thin and smooth, and contains few hairs but many sudoriferous glands; on the lateral side and back of the arm and forearm it is thicker, denser, and contains more hairs but fewer sudoriferous glands. In the region of the olecranon it is thick and rough; it is very loosely connected to the underlying tissue, and falls into transverse wrinkles when the forearm is extended. At the front of the wrist there are three transverse furrows in the skin; they correspond respectively from above downwards to the positions of the styloid process of the ulna, the radiocarpal or wrist-joint, and the midcarpal joint.

The skin of the palm of the hand is hard and dense and covered with a thick layer of epidermis; on the thenar eminence these characteristics are less marked than elsewhere. It is exceedingly sensitive and very vascular, but is destitute of hairs and sebaceous glands. It is tied down by fibrous bands along the lines of flexion of the digits, and exhibits certain furrows of a permanent character. One of these furrows begins in front of the wrist at the tuberosity of the navicular bone, curves round the thenar eminence, and ends on the lateral border of the hand near the level of the metacarpophalangeal joint of the index finger; a second begins at the distal end of the first and extends obliquely across the palm to reach the medial border about the middle of the fifth metacarpal bone; a third begins at the medial border about 2.5 cm. distally to the end of the second, and extends across the heads of the fifth, fourth, and third metacarpal bones. The medial part of the third line and the lateral part of the second line lie in front of the metacarpophalangeal joints of the fingers. The proximal segments of the fingers are joined to one another on the volar aspect by folds of skin constituting the 'web' of the fingers; these folds are about opposite the level of the centres of the proximal phalanges and their free margins are continuous with the transverse furrows at the roots of the fingers. Since the web is confined to the volar aspect, the fingers appear shorter when viewed from in front than from behind. Over the fingers and thumb the skin is thinner, especially at the flexures of the joints (where it is crossed by transverse furrows) and over the terminal phalanges; it is disposed in numerous ridges in consequence of the arrangement of the papillae in it. These ridges form, in different individuals, distinctive and permanent patterns which can be used for purposes of identification.

The superficial fascia in the palm of the hand is made up of dense fibrofatty tissue which binds the skin so firmly to the palmar aponeurosis that very little movement is permitted between the two.

On the back of the hand and fingers the subcutaneous tissue is lax, and the skin is freely movable on the underlying parts. Over the interphalangeal joints it is very loose and is thrown into transverse wrinkles when the fingers are extended.

Bones.—The clavicle can be felt throughout its entire length. The enlarged sternal end projects above the sternum at the side of the jugular notch, and from this the body of the bone can be traced laterally under the skin. The medial part is convex forwards, but the surface is partially obscured by the attachments of the Sternocleidomastoides and Pectoralis major; the lateral end is convex

forwards and ends in a slight enlargement at the acromion of the scapula. The clavicle is almost horizontal when the arm is lying by the side, although in muscular subjects it may incline a little upwards at its acromial end, which is on a plane posterior to the sternal end.

The only parts of the *scapula* that are subcutaneous are the spine and acromion, but the coracoid process, the vertebral border, the inferior angle, and to a lesser extent the axillary border can be readily defined. The acromion and spine are easily recognisable throughout their entire extent, forming with the clavicle the arch of the shoulder. The acromion forms the point of the shoulder; it joins the clavicle at an acute angle—the acromial angle—slightly medially to, and behind the tip of the acromion. The spine can be felt in the floor of an oblique depression and becomes less distinct when traced medialwards; it ends in a slight dimple a little laterally to the spinous process of the third thoracic vertebra. Below this point the vertebral border may be followed downwards and lateralwards to the inferior angle, which is easily identified although covered by the *Latissimus dorsi*. From the inferior angle the axillary border may be traced upwards through its thick muscular covering, forming with its enveloping muscles the posterior fold of the axilla; this fold is more vertical in direction than the anterior fold of the axilla, and can be seen from the front. The coracoid process is situated about 2 cm. below the junction of the intermediate with the lateral third of the clavicle; it is covered by the anterior border of the *Deltoides*, and thus lies a little laterally to the infraclavicular fossa or depression which marks the interval between the *Pectoralis major* and *Deltoides*.

The *humerus* is almost entirely surrounded by muscles, and the only parts which are subcutaneous are its medial and lateral epicondyles; in addition to these, however, the tubercles and a part of the head of the bone can be felt under the skin and muscles by which they are covered. The greater tubercle forms the most prominent bony point of the shoulder, extending beyond the acromion; it is best recognised when the arm is lying passive by the side, for if the arm be raised it recedes under the arch of the shoulder. The lesser tubercle, directed forwards, is medial to the greater and separated from it by the intertubercular sulcus, which can be made out by deep pressure. When the arm is abducted the lower part of the head of the humerus can be felt by pressing deeply in the axilla. On either side of the elbow-joint and just above it are the medial and lateral epicondyles. Of these, the former is the more prominent, but the medial supracondylar ridge is much less marked than the lateral, and as a rule is not palpable; occasionally, however, the hook-shaped supracondylar process (p. 277) is found on this border. The position of the lateral epicondyle is best seen during semiflexion of the forearm, and is indicated by a depression; from it the strongly marked lateral supracondylar ridge runs upwards.

The most prominent part of the *ulna*, the olecranon, can always be identified at the back of the elbow-joint; when the forearm is flexed its upper quadrilateral surface is palpable, but during extension it recedes into the olecranon fossa. During extension the upper border of the olecranon is slightly above the level of the medial epicondyle and nearer to this than to the lateral; when the forearm is fully flexed the olecranon and the epicondyles form the angles of an equilateral triangle. On the back of the olecranon is a smooth triangular subcutaneous surface, and running down the back of the forearm from the apex of this triangle the sinuous dorsal border of the ulna can be felt in its whole length: above, it is situated in the middle of the back of the limb; but below, where it is rounded off, it may be traced to the small subcutaneous surface of the styloid process on the medial side of the wrist. The styloid process forms a prominent tubercle continuous above with the dorsal border and ending below in a blunt apex at the level of the wrist-joint; it is most evident when the hand is in a position midway between supination and pronation. When the forearm is pronated the head of the ulna projects on the back of the wrist; between the head and styloid process of the ulna is the groove which lodges the tendon of the *Extensor carpi ulnaris*.

Below the lateral epicondyle of the humerus a portion of the head of the *radius* is palpable; its position is indicated on the surface by a little dimple which is best seen when the arm is extended. If the finger be placed in this dimple and the semiflexed forearm pronated and supinated the head of the radius will be felt rotating in the radial notch. The upper half of the body of the bone is obscured by muscles; the lower half can be readily examined, and when traced downwards

is found to end in a lozenge-shaped convex surface on the lateral side of the base of the styloid process; this is the only subcutaneous part of the bone, and from its lower end the apex of the styloid process bends medialwards towards the wrist. The styloid process of the radius is about 1.25 cm. below the level of the styloid process of the ulna. About the middle of the dorsal surface of the lower end of the radius is the dorsal radial tubercle, best perceived when the wrist is slightly flexed; it forms the lateral boundary of the oblique groove in which the tendon of the *Extensor pollicis longus* lies.

On the front of the wrist are two subcutaneous eminences, one, on the radial side, the larger and flatter, produced by the tuberosity of the *navicular* bone, and the ridge on the *greater multangular* bone; the other, on the ulnar side, by the *pisiform* bone. The tuberosity of the navicular is distal and medial to the styloid process of the radius, and is most clearly visible when the wrist-joint is extended; the ridge on the greater multangular is about 1 cm. distal to it. The pisiform is about 1 cm. distal to the lower end of the ulna, and just distal to the level of the styloid process of the radius; it is crossed by the uppermost of the three transverse skin furrows on the front of the wrist. The rest of the volar surface of the carpus is covered by tendons and the transverse carpal ligament, and is entirely concealed, with the exception of the hamulus of the *hamate bone*, which however, is difficult to define. On the dorsal surface of the carpus the *triquetral bone* can be clearly made out, and when the wrist-joint is acutely flexed the head of the capitate bone may be felt.

The dorsal surfaces of the *metacarpal bones*, except that of the fifth, are covered by the extensor tendons, and are visible only in very thin hands; the dorsal surface of the fifth is, however, subcutaneous throughout almost its whole length. Slightly lateral to the middle line of the hand is a prominence, frequently well marked, formed by the styloid process of the third metacarpal bone; it is situated about 4 cm. distally to the dorsal radial tubercle. The heads of the metacarpal bones are rounded in contour and stand out in bold relief under the skin when the fist is clenched; the head of the third is the most prominent. In the palm of the hand the metacarpal bones of the fingers are covered by muscles, tendons, and aponeuroses, so that only their heads can be distinguished. The base of the metacarpal bone of the thumb, however, is prominent dorsally, and the body of the bone is easily palpable, ending at the head in a flattened prominence in front of which are the sesamoid bones.

The enlarged ends of the *phalanges* can be easily felt. When the digits are flexed, a slight concavity can be recognised on the distal end of each of the first phalanges; the distal ends of the second phalanges are flattened and square-shaped.

Articulations.—The *sternoclavicular joint* is subcutaneous, and its position is indicated by the enlarged sternal extremity of the clavicle, lateral to the long cord-like sternal head of *Sternocleidomastoideus*. If this muscle be relaxed a depression between the end of the clavicle and the sternum can be felt, defining the exact position of the joint.

The position of the *acromioclavicular joint* is ascertained by determining the slightly enlarged acromial end of the clavicle which projects above the level of the acromion; sometimes this enlargement is so considerable as to form a rounded eminence. The *shoulder-joint* is deeply seated and cannot be palpated.

When the forearm is slightly flexed a curved crease or fold with its convexity downwards is seen in front of the elbow, extending from one epicondyle to the other; the *elbow-joint* is slightly distal to the centre of the fold. The position of the radiohumeral part of the joint can be ascertained by feeling for a slight groove or depression between the head of the radius and the capitulum of the humerus, at the back of the elbow-joint.

The position of the *proximal radio-ulnar joint* is marked on the surface at the back of the elbow by the dimple which indicates the position of the head of the radius. The site of the *distal radio-ulnar joint* can be defined by feeling for the slight groove at the back of the wrist, between the prominent head of the ulna and the lower end of the radius, when the forearm is in a state of almost complete pronation.

Of the three transverse skin furrows on the front of the wrist, the middle corresponds fairly accurately with the *radiocarpal* or *wrist-joint*, and the most distal indicates the position of the *midcarpal articulation*.

The *metacarpophalangeal* and *interphalangeal* joints are readily available for surface examination; the former are situated just distally to the prominences of the knuckles, the latter are sufficiently indicated by the furrows on the volar, and the wrinkles on the dorsal, surfaces.

Muscles (figs. 1153, 1154).—The anterior border of the *Trapezius* presents as a slight ridge running downwards and forwards from the superior nuchal line of

FIG. 1153.—Front of right upper extremity.

the occipital bone to the junction of the intermediate with the lateral third of the clavicle. The inferior border of the muscle forms an undulating ridge passing downwards and medialwards from the root of the spine of the scapula to the spinous process of the twelfth thoracic vertebra.

The lateral border of the *Latissimus dorsi* (fig. 1139) may be traced, when the muscle is in action, as a rounded edge starting from the iliac crest and slanting obliquely forwards and upwards to the axilla, where it takes part with the *Teres major* in forming the posterior axillary fold.

The *Pectoralis major* (fig. 1143) conceals a considerable part of the thoracic wall in front. Its sternal origin presents a border which bounds and determines the width of the sternal furrow. The upper margin is generally well marked near the clavicle, and forms the medial boundary of the infraclavicular fossa, which

FIG. 1154.—Back of right upper extremity.

separates the *Pectoralis major* from the *Deltoides*; it gradually becomes less distinct as it approaches the tendon of insertion and cannot be differentiated from the *Deltoides*. The lower border of the *Pectoralis major* forms the rounded anterior axillary fold. Occasionally a gap is visible between the clavicular and sternal parts of the muscle.

When the arm is raised the lowest slip of origin of the *Pectoralis minor* produces a fulness below the anterior axillary fold and serves to break the sharp outline of the lower border of the *Pectoralis major*.

The origin of the *Serratus anterior* (figs. 1139, 1143) causes a very characteristic surface marking. When the arm is abducted the lower five or six serrations can be seen, separated from those of the *Obliquus externus abdominis* by a zigzag line. When the arm is by the side the highest visible serration is that attached to the fifth rib.

The *Deltoideus* with the underlying prominence of the upper end of the humerus produces the rounded contour of the shoulder; it is rounder and fuller in front than behind, where it presents a somewhat flattened form. Above, its anterior border presents a slightly curved eminence which forms the lateral boundary of the infraclavicular fossa; below, it is closely united with the *Pectoralis major*. Its posterior border is thin, flattened, and scarcely marked above, but is thicker and more prominent below. The insertion of the *Deltoideus* is marked by a depression on the lateral side of the middle of the arm.

Of the scapular muscles the *Teres major* assists the *Latissimus dorsi* to form the thick, rounded, posterior axillary fold.

When the arm is raised the *Coracobrachialis* appears as a narrow elevation emerging from under cover of the anterior axillary fold and running medially to the upper half of the body of the humerus.

On the front and medial aspects of the arm is the prominence of the *Biceps brachii*, bounded on either side by a depression. It determines the contour of the front of the arm and extends from the anterior axillary fold to the bend of the elbow; its upper tendons are concealed by the *Pectoralis major* and *Deltoideus*, and its lower tendon sinks into the cubital fossa. When the muscle is fully contracted it presents a globular form, and the *lacertus fibrosus* (bicipital fascia) attached to its tendon of insertion becomes prominent as a sharp ridge running downwards and medialwards.

On either side of the *Biceps brachii* at the lower part of the arm the *Brachialis* is discernible. Laterally it forms a narrow eminence extending some distance up the arm; medially it produces only a slight fulness above the elbow.

On the back of the arm the long head of the *Triceps brachii* may be seen as a longitudinal eminence, emerging from under cover of *Deltoideus* and gradually passing into the flattened plane of the tendon of insertion of the muscle at the lower part of the back of the arm. When the muscle is in action its medial and lateral heads are prominent.

On the front of the elbow are two muscular elevations, one on either side, which converge below and form the medial and lateral boundaries of the cubital fossa. The medial elevation consists of the *Pronator teres* and the flexors, and is fusiform, pointed above at the medial epicondyle, and gradually tapering off below. The *Pronator teres* is the most lateral of the group, while the *Flexor carpi radialis*, lying to its medial side, is the most prominent and may be traced downwards to its tendon, which is situated nearer to the lateral than to the medial border of the front of the wrist, where it is placed on the medial side of the radial artery and on the lateral side of the median nerve. The *Palmaris longus* presents no surface marking above, but below, its tendon stands out when the muscle is in action as a sharp cord in front of the middle of the wrist. The *Flexor digitorum sublimis* does not directly influence surface form; the position of its four tendons on the front of the lower part of the forearm is indicated by an elongated depression between the tendon of the *Palmaris longus* and that of the *Flexor carpi ulnaris*. The *Flexor carpi ulnaris* determines the contour of the medial border of the forearm, and is separated from the extensor group of muscles by the ulnar furrow the floor of which is formed by the subcutaneous dorsal border of the ulna; its tendon is evident along the ulnar border of the lower part of the forearm, and is most marked when the hand is flexed and adducted.

The elevation on the lateral side of the cubital fossa is produced by the *Brachioradialis*, the extensors, and the *Supinator*; it occupies the lateral and a considerable part of the dorsal surface of the forearm in the region of the elbow, and appears as a fusiform swelling which is on a higher level than that produced by the medial elevation. Its apex is between the *Triceps brachii* and *Brachialis* some distance above the elbow-joint; its greatest breadth is opposite the lateral epicondyle; below this it shades off into a flattened surface. About the middle of the forearm it divides into a lateral and a medial eminence. The lateral eminence consists of the *Brachioradialis*, the *Extensor carpi radialis longus* and the *Extensor carpi radialis brevis*. The medial border of the *Brachioradialis* starts as a rounded

elevation above the lateral epicondyle; lower down, the muscle forms a prominent mass on the radial side of the upper part of the forearm; below, it tapers to its tendon, which may be traced to the base of the styloid process of the radius. The medial eminence comprises the *Extensor digitorum communis*, *Extensor digiti quinti proprius*, and the *Extensor carpi ulnaris*; it begins at the lateral epicondyle of the humerus as a tapering mass which is separated above from the *Anconæus* by a well-marked groove, and below from the *Flexor carpi ulnaris* by the ulnar furrow. The *Anconæus* produces a triangular, slightly elevated area, immediately lateral to the subcutaneous surface of the olecranon and separated from the extensor group by an oblique depression; the upper angle of the triangle is at the dimple behind the lateral epicondyle.

At the lower part of the back of the forearm in the interval between the lateral and medial eminences is an oblique elongated swelling, full above but flattened and partially subdivided below; it is caused by the *Abductor pollicis longus* and the *Extensor pollicis brevis*. It crosses the dorsal and lateral surfaces of the radius to the lateral side of the wrist-joint, whence it is continued to the dorsal surface of the thumb as a ridge which is best marked when the thumb is extended.

The tendons of most of the extensor muscles can be seen and felt on the back of the wrist. Laterally is the oblique ridge produced by the *Extensor pollicis longus*. When the wrist is extended the *Extensor carpi radialis longus* and the *Extensor carpi radialis brevis* can be identified, the one on the lateral and the other on the medial side of the tendon of the *Extensor pollicis longus*. Medially to this the extensor tendons of the fingers can be felt, the *Extensor digiti quinti proprius* being separated from those of the *Extensor digitorum communis* by a slight furrow.

The muscles of the hand are principally concerned, as regards surface form, in producing the thenar and hypothenar eminences, and cannot be individually distinguished; the thenar eminence, on the lateral side, is larger and rounder than the hypothenar, which is a long narrow elevation along the medial side of the palm. When the *Palmaris brevis* is in action it produces a wrinkling of the skin over the proximal part of the hypothenar eminence and a dimple on the medial border of the hand. On the back of the hand the *Interossei dorsales* give rise to elongated swellings between the metacarpal bones; the first forms a prominent fusiform bulging when the thumb is adducted, the others are not so marked.

Arteries.—Above the middle of the clavicle the pulsation of the *subclavian artery* can be detected by pressing downwards, backwards, and medialwards against the first rib. The pulsation of the *axillary artery*, where the vessel crosses the second rib, can be felt below the middle of the clavicle medially to the coracoid process; along the lateral wall of the axilla the course of the artery can be easily followed close to the medial border of the *Coracobrachialis*. The *brachial artery* can be recognised along the medial margin of the *Biceps brachii*; in the upper two-thirds of the arm it lies on the medial side of the humerus, but in the lower third is more directly in front of the bone. In front of the lower end of the radius, between the styloid process and *Flexor carpi radialis*, a portion of the *radial artery* is superficial and is used clinically for observations on the pulse.

Veins.—The superficial veins of the upper extremity are easily rendered visible by compressing the proximal trunks near the axilla; their arrangement is described on pp. 687 to 689.

Nerves.—The uppermost trunks of the *brachial plexus* can be felt for a short distance above the clavicle as they emerge from under the lateral border of *Sternocleidomastoideus*; the larger nerves derived from the plexus can be rolled under the finger against the lateral axillary wall, but cannot be separately identified. The *ulnar nerve* can be detected in the sulcus *nervi ulnaris* behind the medial epicondyle of the humerus, but is more easily felt about 2 cm. below the elbow-joint.

SURFACE MARKINGS OF THE UPPER EXTREMITY

Bony landmarks.—The bony landmarks as described above are so readily available for surface recognition that no special measurements are required to indicate them. It may be noted, however, that the medial angle of the scapula is applied to the second rib, while the inferior angle lies against the seventh. The intertubercular sulcus of the humerus is below the acromioclavicular joint when the arm hangs by the side of the body with the palm of the hand forwards.

Articulations.—The *acromioclavicular joint* is situated in a plane passing sagittally through the middle line of the front of the arm. The line of the *elbow-joint* is not straight; the humeroradial portion is practically at right angles to the long axis of the humerus, and is situated about 2 cm. distally to the lateral epicondyle;

FIG. 1155.—The mucous sheaths of the tendons on the front of the wrist and digits.

the humero-ulnar portion is oblique, and its medial end is about 2.5 cm. distally to the medial epicondyle. The position of the *wrist-joint* can be indicated by drawing a curved line, with its convexity upwards, between the styloid processes of the radius and ulna; the summit of the convexity is about 1 cm. above the centre of a straight line joining the two processes.

Muscles.—The only muscles of the upper extremity which occasionally require definition by surface lines are the Trapezius, the Latissimus dorsi and the Pectorales

major and minor. The anterosuperior border of the *Trapezius* is indicated by a line from a point about 3 cm. laterally to the external occipital protuberance to the junction of the intermediate with the lateral third of the clavicle; the line of the lower border extends from the spinous process of the twelfth thoracic vertebra

FIG. 1156.—The mucous sheaths of the tendons on the back of the wrist.

to the root of the spine of the scapula. The upper border of the *Latissimus dorsi* is almost horizontal, running from the spinous process of the seventh thoracic vertebra to the inferior angle of the scapula and thence somewhat obliquely to the intertubercular sulcus of the humerus; the lower border corresponds roughly to a line drawn from the iliac crest about 2 cm. from the lateral margin of the *Sacrospinalis* to the intertubercular sulcus of the humerus. The upper margin of the *Pectoralis major* extends from the middle of the clavicle to the surgical neck

of the humerus ; its lower border is practically in the line of the fifth rib and reaches from the fifth costochondral junction to the middle of the anterior border of the Deltoides. The lines indicating the upper and lower borders of the *Pectoralis minor* begin at the coracoid process of the scapula and extend to the third and fifth ribs respectively, just laterally to the corresponding costal cartilages. On

FIG. 1157.—Front of right upper extremity, showing surface markings for bones, arteries, and nerves.

the front of the elbow-joint a triangular space—the cubital fossa—is mapped out for convenience of reference. The base of the triangle is a line joining the medial and lateral epicondyles of the humerus, while the sides are formed respectively by the salient margins of the Brachioradialis and Pronator teres.

Mucous sheaths.—On the volar surfaces of the wrist and hand the mucous sheaths of the flexor tendons (fig. 1155) can be indicated as follows. The sheath for the Flexor pollicis longus extends from a point about 3 cm. above the upper edge of the transverse carpal ligament to the terminal phalanx of the thumb. The common sheath for the tendons of the Flexor digitorum sublimis and Flexor digitorum profundus reaches about 4 cm. above the upper edge of the transverse carpal ligament, and extends into the palm to about the level of the centres of the metacarpal bones. The sheath for the tendons to the little finger is continued from the common sheath

FIG. 1158.—Back of right upper extremity, showing surface markings for bones and nerves.

to the base of the terminal phalanx of this finger ; the sheaths of the tendons to the index, middle and ring fingers are separated from the common sheath by an interval ; they begin opposite the necks of the metacarpal bones and extend to the terminal phalanges. The mucous sheaths of the extensor tendons are shown in fig. 1156 (see also pp. 503, 504).

Arteries (fig. 1157).—The course of the *axillary artery* can be indicated by abducting the arm to a right angle and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence of

the Coracobrachialis. Of the branches of the axillary artery, the origin of the *thoraco-acromial* corresponds to the point where the axillary artery is crossed by the upper border of the Pectoralis minor; the *lateral thoracic* follows the line of the lower border of the Pectoralis minor; the *subscapular* is sufficiently indicated by the axillary border of the scapula; the *scapular circumflex* is given off the subscapular opposite the midpoint of a line joining the tip of the acromion to the lower edge of the deltoid tuberosity, while the *humeral circumflex* arteries arise from the axillary artery about 2 cm. above this. The course of the *brachial artery* is marked by a line drawn from the medial border of the Coracobrachialis at the level of the posterior axillary fold to a point in front of the elbow-joint midway between the epicondyles of the humerus, and continued distally for 2.5 cm., where the artery bifurcates. With regard to the branches of the brachial artery—the *arteria profunda brachii* crosses the back of the humerus at the level of the insertion of Deltoides; the *nutrient artery* arises opposite the middle of the body of the humerus; a line from this point to the back of the medial epicondyle represents the *superior ulnar collateral artery*; the *inferior ulnar collateral artery* arises about 5 cm. above the fold of the elbow-joint and runs medialwards.

The position of the *radial artery* in the forearm is represented by a line from the lateral margin of the tendon of the Biceps brachii in the centre of the cubital fossa, to the medial side of the front of the styloid process of the radius. The situation of the distal portion of the artery is indicated by continuing this line round the radial side of the wrist to the proximal end of the first intermetacarpal space.

On account of the curved direction of the *ulnar artery*, two lines are required to indicate its course in the forearm; one is drawn from the front of the medial epicondyle of the humerus to the radial side of the pisiform bone; the distal two-thirds of this line represent the distal two-thirds of the artery; the proximal third is represented by a line, convex medialwards, from the centre of the hollow in front of the elbow-joint to the junction of the upper with the middle third of the first line.

The position of the *superficial volar arch* (fig. 1159) is indicated by a line starting from the radial side of the pisiform bone, running distalwards for about one-half of the length of the palm, and then lateralwards as far as the base of the thumb, with its convexity towards the fingers. The summit of the arch is usually on a level with the distal border of the outstretched thumb. The *deep volar arch* is transverse in direction, and is situated about 1 cm. nearer to the carpus.

Nerves (figs. 1157, 1158).—In the arm the line of the *median nerve* is that for the brachial artery; at the upper part of the arm it is lateral to the artery, whereas at the bend of the elbow it is medial to it. The course of the nerve in the forearm is marked by a line starting from a point just medially to the centre of one joining the epicondyles, and extending to the lateral margin of the tendon of the Palmaris longus at the wrist.

FIG. 1159.—Palm of left hand, showing position of skin creases and bones, and surface markings for the volar arches.

The *ulnar nerve* follows the line of the brachial artery in the upper half of the arm, but at the middle of the arm it leaves the artery and descends to the back of the medial epicondyle. In the forearm it is represented by a line from the front of the medial epicondyle to the lateral side of the pisiform bone.

The course of the *radial nerve* can be indicated by a line drawn from just below the posterior axillary fold, to the lateral side of the humerus at the junction of its middle with its lower third; thence it passes vertically downwards on the front of the arm to the level of the lateral epicondyle. The course of the *superficial radial nerve* is represented by a continuation of this line to the junction of the middle with the lower third of the radius; it then crosses the lateral border of the radius and runs distalwards to the dorsum of the base of the first metacarpal bone.

The *axillary nerve* crosses the humerus about 2 cm. above the centre of a line joining the tip of the acromion to the lower edge of the deltoid tuberosity.

SURFACE ANATOMY OF THE LOWER EXTREMITY

Skin.—The skin on the medial side of the thigh and in the hollow of the groin is thin, smooth, and elastic, and contains few hairs except in the neighbourhood of the os pubis; on the lateral side of the thigh it is thicker and the hairs are more numerous. At the junction of the front of the thigh with the abdomen is a well-defined furrow which indicates the site of the inguinal ligament; the furrow presents a general convexity downwards, but its medial half, which is the better marked, is nearly straight. The skin of the buttock is fairly thick and as a rule is destitute of conspicuous hairs except towards the post-anal furrow, where in some males they are abundantly developed. An almost transverse fold—the *fold of the buttock* or *gluteal fold*—crosses the lower part of the buttock; it practically bisects the lower margin of the Glutæus maximus and is most evident when the hip-joint is extended. The skin over the front of the knee is covered by thickened epidermis; it is loose and is thrown into transverse wrinkles when the leg is extended. The skin of the leg is thin, especially on the medial side, and is covered with numerous large hairs. On the dorsum of the foot the skin is thin, loosely connected to subjacent parts, and contains few hairs; on the plantar surface, and especially over the heel, the epidermis is of great thickness, and here, as in the palm of the hand, there are neither hairs nor sebaceous glands.

Bones.—The *hip-bones* are largely covered with muscles, and only approach the surface at a few points. In front, the anterior superior iliac spine is easily recognised, and in thin subject, stands out as a prominence at the lateral end of the fold of the groin; in fat subjects its position is indicated by an oblique depression, at the bottom of which the bony process can be felt. Proceeding upwards and backwards from the anterior superior iliac spine the sinuously curved iliac crest can be traced to the posterior superior iliac spine, the site of which is indicated by a slight depression; on the outer lip of the crest, about 5 cm. behind the anterior superior spine, is the iliac tubercle. In thin subjects the pubic tubercle is very apparent, but in the obese it is obscured by the pubic fat; it can, however, be detected by following the tendon of origin of the Adductor longus. Another part of the hip-bone which is accessible to touch is the ischial tuberosity, situated beneath the Glutæus maximus, and easily felt when the hip-joint is flexed, as it is then uncovered by muscle.

The *femur* is enveloped by muscles, so that the only subcutaneous parts of it are the lateral surface of the greater trochanter and the lower expanded end of the bone. The site of the greater trochanter is generally indicated by a depression owing to the thickness of the Glutæus medius and Glutæus minimus which project above it; when, however, the thigh is flexed, and especially if it be crossed over the opposite one, the trochanter produces a blunt eminence on the surface. The lateral condyle is more easily felt than the medial; both epicondyles can be readily identified, and at the upper part of the medial condyle the sharp adductor tubercle can be recognised without difficulty. When the knee is flexed a portion of the patellar surface of the femur is uncovered and is palpable.

The anterior surface of the *patella* is subcutaneous. When the knee is extended the medial border of the bone is a little more prominent than the lateral, and if the Quadriceps femoris be relaxed the bone can be moved from side to side. When

the joint is flexed the patella recedes into the hollow between the femoral condyles and the upper end of the tibia, and is firmly applied to the femur.

A considerable portion of the *tibia* is subcutaneous. At the upper end the condyles can be felt just below the knee; the medial condyle is broad and smooth, and merges below into the subcutaneous surface of the body or shaft of the bone; the lateral is narrower and more prominent, and on it, about midway between the apex of the patella and the head of the fibula, is the tubercle for the attachment of the iliotibial tract of the fascia lata of the thigh. In front of the upper end of the bone, between the condyles, is the tuberosity, which is continuous below with the anterior crest of the bone. This crest can be identified in the upper two-thirds of its extent as a flexuous ridge, but in the lower third it disappears and the bone is concealed by the tendons of the muscles on the front of the leg. Medially to the anterior crest is the broad subcutaneous surface. The medial malleolus forms a broad prominence, situated at a higher level and somewhat farther forward than the lateral malleolus; its anterior border is nearly straight; on its posterior is a sharp edge which forms the medial margin of the groove for the tendon of the Tibialis posterior.

The only subcutaneous parts of the *fibula* are the head, the lower part of the body or shaft, and the lateral malleolus. The head lies behind and laterally to the lateral condyle of the tibia, and appears as a small prominent pyramidal eminence slightly above the level of the tibial tuberosity; its position can be readily located by following the tendon of Biceps femoris downwards. The lateral malleolus is a narrow elongated prominence from which the lower third or half of the lateral surface of the body of the bone can be traced upwards.

On the dorsum of the tarsus the individual bones cannot be distinguished, with the exception of the head of the *talus* which forms a rounded projection in front of the ankle-joint when the foot is extended. The whole dorsal surface of the foot has a smooth convex outline, the summit of which is the ridge formed by the head of the talus, the navicular, the second cuneiform, and the second metatarsal bone; from this it inclines gradually lateralwards, and rapidly medialwards. On the medial side of the foot the medial process of the tuberosity of the *calcaneus* and the ridge separating the posterior from the medial surface of the bone are distinguishable; in front of this, and below the medial malleolus, is the sustentaculum tali. The tuberosity of the *navicular* is palpable about 2.5 cm. in front of the medial malleolus.

Farther forwards, the ridge formed by the base of the *first metatarsal* bone can be obscurely felt, and from this the body of the bone can be traced to the expanded

FIG. 1160.—Front and medial aspect of right thigh.

head: beneath the base of the first phalanx is the medial sesamoid bone. On

FIG. 1161.—Back of left lower extremity.

the lateral side of the foot, the most posterior bony point is the lateral process of the tuberosity of the calcaneus, with the ridge separating the posterior from the lateral surface of the bone. In front of this the greater part of the lateral surface of the calcaneus is subcutaneous; on it, below and in front of the lateral malleolus, the trochlear process, when present, can be felt. Farther forwards the base of the fifth metatarsal bone is prominent, and from it the body of the bone can be traced forwards to the head.

As in the case of the metacarpals, the dorsal surfaces of the metatarsal bones are easily defined, although their heads do not form prominences: the plantar surfaces are obscured by muscles. The phalanges in their whole extent are readily palpable.

Articulations. -- The hip-joint is deeply seated and cannot be palpated.

The interval between the tibia and femur, indicating the level of the knee-joint, can always be easily felt. When the knee is semi-flexed, the medial border of the patella, the medial condyle of the femur, and the upper border of the medial condyle of the tibia, bound a triangular depressed area which indicates the position of the joint and is in front of the anterior end of the medial meniscus.

The ankle-joint can be felt on either side of the Extensor tendons, and during extension of the joint the superior articular surface of the talus projects below the anterior border of the lower end of the tibia.

Muscles.—Of the muscles of the thigh, those of the anterior femoral region (fig. 1160) contribute largely to surface form. The *Tensor fasciæ latæ* produces a broad elevation immediately below the anterior part of the iliac crest and behind the anterior superior iliac spine; from its lower border a groove caused by the iliotibial tract of the fascia lata extends downwards to the lateral side of the knee-joint. The upper portion of the *Sartorius* constitutes the lateral boundary of the femoral triangle, and, when the muscle is in action, forms a prominent oblique ridge which is continued below into a flattened plane and then gradually merges into a general fulness on the medial side of the knee-joint. When the *Sartorius* is not in action, a depression exists between the *Quadriceps femoris* and the *Adductores* and extends obliquely downwards and medialwards from the apex of the femoral triangle to the side of the knee. In the angle between the *Sartorius* and *Tensor fasciæ latæ*, just below the anterior superior iliac spine, the *Rectus femoris* appears, and its borders can be defined when the muscle is in action. The *Vastus lateralis* forms a long flattened plane traversed by the groove of the iliotibial tract. The *Vastus medialis* causes a considerable prominence on the medial side of the lower half of the thigh; this prominence increases towards the knee and ends somewhat abruptly with a full curved outline. The *Vastus intermedius* is completely hidden. The *Adductores* cannot be differentiated from one another, with the exception of the tendon of origin of the *Adductor longus* and the lower tendon of the *Adductor magnus*. When the *Adductor longus* is in action its tendon of origin stands out as a prominent ridge running obliquely downwards and lateralwards from the neighbourhood of the pubic tubercle, and forming the medial border of the femoral triangle. The lower tendon of the *Adductor magnus* is felt as a short ridge extending downwards between the *Sartorius* and *Vastus medialis* to the adductor tubercle on the medial condyle of the femur. The *Adductores* fill the triangular space at the upper part of the thigh, between the femur and the pelvis, and to them is due the contour of the medial border of the thigh, the *Gracilis* contributing largely to the smoothness of the outline.

The *Glutæus maximus* (fig. 1161) forms the full rounded outline of the buttock; it is prominent behind, compressed in front, and ends at its tendinous insertion in a depression immediately behind the greater trochanter; its lower border crosses the glutæal fold obliquely downwards and lateralwards; the lower part of its medial border is separated from the corresponding part of the opposite muscle by the deep glutæal cleft. The upper part of the *Glutæus medius* is visible, but its lower part, together with the *Glutæus minimus* and the external rotators of the thigh, is completely hidden. The hamstring muscles appear from beneath the lower margin of the *Glutæus maximus*; at first they are narrow and not well defined, but as they descend they become more prominent and eventually divide into two well-marked ridges formed by their tendons; these constitute the upper

FIG. 1162.—Lateral aspect of right leg.

boundaries of the popliteal fossa. The tendon of the *Biceps femoris* is a thick cord running to the head of the fibula: the tendons of the *Semimembranosus* and *Semitendinosus* run medialwards to the tibia and are separated by a slight furrow; the *Semitendinosus* is the more superficial, and can be felt in certain positions of the limb as a sharp cord, while the *Semimembranosus* is thick and rounded. The *Gracilis* is situated a little in front of them.

The *Tibialis anterior* (fig. 1162) presents a fusiform enlargement at the lateral side of the tibia and projects beyond the anterior crest of the bone; its tendon can be traced on the front of the tibia and ankle-joint and thence along the medial side of the foot to the base of the first metatarsal bone. The fleshy fibres of the *Peronæus longus* are strongly marked at the upper part of the lateral side of the leg: it is

FIG. 1163.—The mucous sheaths of the tendons round the ankle. Lateral aspect.

separated by furrows from the *Extensor digitorum longus* in front and the *Soleus* behind. Below, the fleshy fibres end abruptly in a tendon which overlaps the more flattened elevation of the *Peronæus brevis*; below the lateral malleolus the tendon of the *Peronæus brevis* is the more marked.

On the dorsum of the foot (fig. 1163) the tendons emerging from beneath the transverse and cruciate crural ligaments spread out and can be distinguished as follows: the most medial and largest is the *Tibialis anterior*, the next is the *Extensor hallucis proprius*, then the *Extensor digitorum longus* dividing into four tendons to the second, third, fourth, and fifth toes, and lastly the *Peronæus tertius*. The *Extensor digitorum brevis* produces a rounded outline on the dorsum of the foot and a fulness in front of the lateral malleolus. The *Interossei dorsales* bulge between the metatarsal bones.

At the back of the knee is the popliteal fossa, bounded above by the tendons of the hamstrings and below by the *Gastrocnemius*. Below this fossa is the prominent fleshy mass of the calf of the leg produced by the *Gastrocnemius* and *Soleus* (fig. 1161). When these muscles are in action the borders of the *Gastrocnemius* form two well-defined curved lines which converge to the tendo calcaneus; the medial border is the more prominent. At the same time the edges of the *Soleus* form, on either side of the *Gastrocnemius*, curved eminences, of which the lateral is the longer. The fleshy mass of the calf ends somewhat abruptly in the tendo calcaneus, which tapers in the upper three-fourths of its extent but widens out slightly below. When the *Tibialis posterior* is in action, its tendon produces a well-defined ridge behind the medial border of the lower part of the tibia.

• On the sole of the foot the *Abductor digiti quinti* forms a narrow rounded

elevation on the lateral side, and the *Abductor hallucis* a lesser elevation on the medial side. The *Flexor digitorum brevis*, bound down by the plantar aponeurosis, is not very apparent; it produces a flattened form, and the thickened skin underlying it is thrown into numerous wrinkles.

Arteries.—The *femoral artery* is readily felt as it crosses the brim of the pelvis; in its course down the thigh its pulsation becomes gradually more difficult of recognition. When the knee is flexed the pulsation of the *popliteal artery* can easily be detected in the popliteal fossa.

The *anterior tibial artery* is superficial on the lower part of the front of the tibia and can be traced over the ankle into the *dorsalis pedis artery*: the latter can be followed to the proximal end of the first intermetatarsal space. The pulsation

FIG. 1164.—The mucous sheaths of the tendons round the ankle. Medial aspect.

of the *posterior tibial artery* is evident near the lower end of the back of the tibia, and is easily detected behind the medial malleolus.

Veins.—By compressing the proximal trunks, the venous arch on the dorsum of the foot and the great and small saphenous veins (see pp 695, 696) are rendered visible.

Nerves.—The only nerves of the lower extremity which can be located by palpation are the (1) *common peroneal nerve* as it winds round the lateral side of the neck of the fibula, and (2) the *tibial nerve* as it descends behind the lower end of the tibia.

SURFACE MARKINGS OF THE LOWER EXTREMITY

Bony landmarks.—The anterior superior iliac spine is at the level of the sacral promontory—the posterior at the level of the spinous process of the second sacral vertebra. A horizontal line through the highest points of the iliac crests passes also through the spinous process of the fourth lumbar vertebra, while, as already pointed out (p. 1235), the transtubercular plane through the tubercles on the iliac crests cuts the body of the fifth lumbar vertebra. The upper margin of the greater sciatic notch is opposite the spinous process of the third sacral vertebra, and slightly below this level is the posterior inferior iliac spine. The surface markings of the posterior inferior iliac spine and the ischial spine are in a line which joins the posterior superior iliac spine to the outer part of the ischial tuberosity; the posterior inferior spine is 5 cm. and the ischial spine 10 cm. below the posterior superior spine; the ischial spine is opposite the first piece of the coccyx.

With the body in the erect posture the line joining the pubic tubercle to the top of the greater trochanter is nearly horizontal; the middle of this line overlies the acetabulum and the head of the femur.

A line used for clinical purposes is that of Nélaton (fig. 1165), which is drawn from the anterior superior iliac spine to the most prominent part of the ischial tuberosity; it crosses the centre of the acetabulum and the upper border of the greater trochanter. Another surface marking of clinical importance is Bryant's triangle, which is mapped out thus: a line from the anterior superior iliac spine to the top of the greater trochanter forms the base of the triangle; its sides are formed respectively by a horizontal line carried backwards from the anterior superior iliac spine and a vertical line from the top of the greater trochanter.

FIG. 1165.—Nélaton's line and Bryant's triangle.

Articulations.—The posterior superior iliac spine overlies the centre of the *sacro-iliac articulation*.

¶ The *hip-joint* may be indicated, as described above, by the centre of a horizontal line from the pubic tubercle to the top of the greater trochanter; or by a point below and slightly lateral to the middle of the inguinal ligament. The *knee-joint* is superficial and requires no surface marking. The level of the *ankle-joint* is that of a transverse line about 1 cm. above the level of the tip of the medial malleolus. If the foot be extended, the head of the talus appears as a rounded prominence on the medial side of the dorsum; between it and the tuberosity of the navicular is the *talonavicular joint*. The *calcaneocuboid joint* is midway between the lateral malleolus and the prominent base of the fifth metatarsal bone; the line indicating it is parallel to that of the talonavicular joint. The line of the *fifth tarsometatarsal joint* is very oblique; it starts behind the projection of the base of the fifth metatarsal bone, and if continued would pass through the head of the first metatarsal. The lines of the *fourth* and *third tarsometatarsal joints* are less oblique. The *first tarsometatarsal joint* corresponds to a groove which can be felt by making firm pressure on the medial border of the foot 2.5 cm. in front of the tuberosity of the navicular; the position of the *second tarsometatarsal joint* is 1.25 cm. behind this. The *metatarsophalangeal joints* are about 2.5 cm. behind the webs of the corresponding toes.

Muscles.—The muscles do not require surface lines to indicate them, but there are three intermuscular spaces which must be identified, viz.: the femoral triangle, the adductor canal, and the popliteal fossa.

The *femoral triangle* is bounded above by the inguinal ligament, laterally by the medial border of the Sartorius, and medially by the medial border of the Adductor longus. In the triangle is the fossa ovalis (saphenous opening), through which the great saphenous vein dips to join the femoral; the centre of this fossa is about 4 cm. below and lateral to the pubic tubercle, its vertical diameter measures about 4 cm. and its transverse about 1.5 cm. The centre of the femoral ring is about 1.25 cm. lateral to the pubic tubercle.

The *adductor canal* occupies the medial part of the middle third of the thigh; it begins at the apex of the femoral triangle and lies deep to the vertical part of the

FIG. 1166.—Front of right thigh, showing surface markings for bones, femoral artery, and femoral nerve.

FIG. 1167.—Lateral aspect of right leg, showing surface markings for bones, anterior tibial and dorsalis pedis arteries, and deep peroneal nerve.

Sartorius. The *popliteal fossa* is bounded, above and medially by the tendons of the Semimembranosus and Semitendinosus, above and laterally by the tendon of the Biceps femoris, below and medially by the medial head of the Gastrocnemius, below and laterally by the lateral head of the Gastrocnemius and the Plantaris.

Mucous sheaths.—The positions of the mucous sheaths round the tendons about the ankle-joints are sufficiently indicated in figs. 1163, 1164 (see also pp. 536, 537).

Arteries.—The points of emergence of the three main arteries on the buttock, viz. the superior and inferior gluteal arteries and the internal pudendal artery, may be indicated in the following manner (fig. 1168). With the femur slightly flexed and rotated inwards, a line is drawn from the posterior superior iliac spine to the posterior superior angle of the greater trochanter; the point of emergence of the *superior gluteal artery* from the upper part of the greater sciatic foramen

corresponds to the junction of the upper with the middle third of this line. A second

FIG. 1168.—Back of left lower extremity, showing surface markings for bones, vessels, and nerves.

line is drawn from the posterior superior iliac spine to the outer part of the ischial tuberosity; the point of emergence of the *inferior gluteal* and *internal pudendal* arteries from the lower part of the greater sciatic foramen corresponds to the junction of its middle with its lower third. The course of the *femoral artery* (fig. 1166) is represented by the upper two-thirds of a line from a point midway between the anterior superior iliac spine and the symphysis pubis to the adductor tubercle of the femur, with the thigh abducted and rotated outwards; the *profunda femoris* rises from it about 3 cm. below the inguinal ligament. The course of the upper part of the *popliteal artery* (fig. 1168) is indicated by a line from the lateral margin of the Semimembranosus at the junction of the middle with the lower third of the thigh to the middle of the popliteal fossa; from this point it runs vertically downwards to the level of a line through the lower part of the tibial tuberosity. The line indicating the *anterior tibial artery* (fig. 1167) is drawn from the medial side of the head of the fibula to a point midway between the malleoli; the artery begins about 3 cm. below the head of the fibula. The *dorsalis pedis artery* is represented by a line from the centre of the interval between the malleoli to the proximal end of the first intermetatarsal space.

The course of the *posterior tibial artery* (fig. 1168) can be shown by a line from the end of the popliteal artery, i.e. 2.5 cm. below the centre of the popliteal fossa, to midway between the tip of the medial malleolus and the centre of the convexity of the heel; its main branch, the *peroneal artery*, begins about 7 or 8 cm. below the level of the knee-joint and follows the line of the fibula to the back of the lateral malleolus. The *medial*

and *lateral plantar arteries* begin from the end of the posterior tibial; the medial extends to the middle of the ball of the great toe, the lateral to within a finger's breadth of the tuberosity of the fifth metatarsal bone; from this latter point the *plantar arch* crosses the foot to the proximal end of the first intermetatarsal space.

Veins.—The line of the *great saphenous vein* is from the front of the medial malleolus to the centre of the fossa ovalis (saphenous opening); the *small saphenous vein* runs from the back of the lateral malleolus to the centre of the popliteal fossa.

Nerves.—When the thigh is rotated outwards the course of the *sciatic nerve* (fig. 1168) can be indicated by a line from a point midway between the outer border of the ischial tuberosity and the posterior superior angle of the greater trochanter to the upper angle of the popliteal fossa. The continuation of this line vertically through the centre of the popliteal fossa represents the position of the *tibial nerve*, while the *common peroneal nerve* follows the line of the tendon of the Biceps femoris. The lines for the *deep peroneal nerve* and the continuation of the *tibial nerve* correspond respectively to those for the anterior and posterior tibial arteries.

INDEX

- Trachelomastoidous muscle,** 447
Tracheobronchial lymph-glands, 737
 applied anatomy of, 737
Tracheotomy, 1031
Trachoma glands, 976
Tract or tracts—
 anterior basis bundle, 755
 anterior proper, 755
 of Burdach, 756
 cerebellospinal of Löwenthal, 755
 cerebrospinal, anterior, 754
 lateral, 755
 comma-shaped, 758
 cornucommissural, 757
 crossed pyramidal, 755
 direct cerebellar of Flechsig, 756
 pyramidal, 754
 dorsal peripheral band, 758
 of Goll, 756
 of Gowers, 756
 iliotibial, 516
 lateral basis bundle, 756
 lateral proper, 756
 of Lissauer, 756
 motor, 835
 olfactory, 812
 olivospinal (Helweg), 756
 optic, 802
 oval area of Flechsig, 758
 rubrospinal of Monakow, 755
 secondary sensory, 756
 sensory, 836
 spinocerebellar, anterior, 756
 spinotroctal, 756
 spinothalamic, 756
 tectospinal, 755, 756
 triangular strand, 758
 vestibulospinal, 755
Traction epiphyses, 24
Tractus peduncularis transversus, 788*
 solitarius, 91
 spiralis foraminosus, 207, 995, 1004
Tragicus muscle, 981
Tragus, 979
Transitional epithelium, 7
Transpyloric plane, 1084
Transversa colli artery, 611
Transversalis cervicis muscle, 447
 fascia, 465
Transverso acetabular ligament, 396
 carpal ligament, 500
 cervical artery, 611
 ascending branch, 611
 descending branch, 611
 nerve, 893
 colon, 1118
 crural ligament, 535
 diameter of pelvis, 305
 facial artery, 586
 vein, 674
 fasciculi, superficial of hand, 505
 fibres of cerebral hemispheres, 828
 fissure of brain, 827
 of liver, 1135
 folds of rectum, 1120
 humeral ligament, 370
Transverse ligament of atlas, 355
 crus inferius, 355
 crus superius, 355
 inferior, of distal tibio-fibular articulation, 410
 of knee, 405
 metacarpal, 386
 metatarsal, 410
 of pelvis, 476
 ligaments of scapula, 368, 369
 mesocolon, 1096
 occipital sulcus, 809
 processes of a vertebra, 162
 scapular artery, 610
 sinus of pericardium, 552
 sinuses of dura mater, 681
 sulci, 194
 temporal gyri, 810
Transversus abdominis muscle, 462
 auriculæ muscle, 981
 linguæ, 1069
 menti muscle, 431
 nuchæ muscle, 427
 pedis muscle, 540
 perinæi profundus muscle, in female, 477
 in male, 476
 perinæi superficialis muscle, in female, 476
 in male, 473
 thoracis muscle, 451
Trapezium, 292
Trapezius muscle, 478
Trapezoid, 292
 body, 773
 ligament, 367
 nucleus, 773
 ridge, 271
Treves, bloodless fold of, 1098
Triangle of auscultation, 480, 1229
 Bryant's 1260
 carotid, 592
 inferior, 592
 deltoideopectoral, 483
 digastric, 592
 femoral, 654
 of Hesselbach, 1126
 lumbar, 480
 muscular, 592
 of neck, anterior, 591
 posterior, 593
 occipital, 593
 of Petit, 480
 Scarpa's, 654
 subclavian, 593
 submaxillary, 592
 suboccipital, 449
 suprahyoid, 593
 suprapectoral, 203, 248
Triangular fascia, 460
 ligament, 475
 deep layer of, 476
 superficial layer of, 475
 left, of liver, 1087, 1137
 right, of liver, 1087, 1137
 strand, 758
Triangularis muscle, 430
sterni muscle, 451
Triceps brachii muscle, 490
 applied anatomy of, 491
 sural muscle, 240
Trichterbrust, 192
Tricuspid valve, 558
Trigeminal impression,* 207
Trigeminal nerve, 853
 applied anatomy of, 863
 surface marking of, 1217
 reflexes, 864
Trigone, olfactory, 812
Trigonum collaterale, 819
 habenulæ, 797
 hypoglossi, 768, 786, 882
 vagi, 768
 vesicæ, 1158
Trigonum fibrosum of heart, 562
Triquetral bone, 291
 ossification of, 296
Trochanter, greater, 311
 lesser, 312
 third, 312
Trochanteric fossa, 311

 of penis, 701
 venous arch, 687
 network, 687
 emissary, 686
 applied anatomy of, 687
 epigastric, inferior, 692
 superficial, 696
 facial, anterior, 673
 applied anatomy, 1154
 common, 673
 deep, 674
 posterior, 674
 transverse, 674
 femoral, 698
 frontal, 672
 of Galeo, 680
 gastric, right, 706
 short, 705
 gastro-epiploic, left, 705
 right, 706
 gluteal, 700
 great cardiac, 672
 hæmorrhoidal, inferior, 700
 middle, 700
 plexus, 700
 applied anatomy of, 701
 superior, 705
 of hand, 687, 690
 of head and neck, 672
 of heart, 671
 hemiazygos, 693
 accessory, 693
 hepatic, 703
 histology of, 549
 hypogastric, 690
 iliac, circumflex, deep, 699
 superficial, 696
 com, 70
 external, 698
 internal, 699
 inferior cava, 701
 innominate, 691
 intercapitular, 687, 695, 698
 intercostal, 693
 interlobular, of kidney, 1150
 of liver, 1139
 internal mammary, 691
 intervertebral, 695
 intralobular, of liver, 703,
 1139

articular septum, muscular, 565
 atole, 565
 articularis muscle, 1026
 cinctus, 1098
 ventricle of, 824
 articular fossa, 194
 uniform process or appendix, 1116
 lymphatic vessels of, 731
 structure of, 1117
 axis of cerebellum, inferior, 775, 787
 superior, 775, 776
 foramina, 85
 articular, antecubital, 167*
 eleventh thoracic, 169
 fifth lumbar, 170
 first cervical, 164
 first thoracic, 168
 ninth thoracic, 169
 prominens, 166
 ossification of, 178
 second cervical, 165
 seventh cervical, 166
 tenth thoracic, 169
 twelfth thoracic, 169
 Vertebra, 161
 articular processes of, 162
 bodies of, 161
 cervical, 162
 cervicales, 162
 coccygeal, 178
 false or fixed, 161
 general characteristics of, 161
 laminae of, 162
 ligaments of, 349
 lumbales, 169
 lumbar, 169
 ossification of, 176
 pedicles of, 161
 sacral, 171
 spinous processes of, 162
 structure of, 162
 thoracales, 167
 thoracic, 167
 transverse processes of, 162
 true or movable, 161
 Vertebral arch, 161
 arches, articulations of, 351
 pedicles or roots of, 161
 artery, 606
 body, 161
 canal, 181
 column, 161, 179
 applied anatomy of, 181
 articulations of, 348
 cartilaginous, 70
 curves of, 179
 development of, 69
 fracture-dislocation of, 181
 kyphosis of, 181
 laminectomy, 182
 lateral curvature of, 179, 181
 lordosis of, 181
 membranous, 69
 ossification of, 176
 surface anatomy of, 1224
 veins of, 694
 foramen, 161
 foramen, 180
 muscles, anterior, 442
 lateral, 444
 notches, 162
 ribs, 186, 365
 vein, 678

Vertebral column, 161, 179
 venous plexuses, 694
 Vertebrochondral ribs, 186, 364
 Vertebrocostal ribs, 364
 Vertical circumference of skull, 261
 index of skull, 261
 part of palatine bone, 231
 Verticalis linguae, 1069
 Verumontanum, 1181
 Vesica folles, 1140
 urinaria, 1154
 Vesical artery, inferior, 645
 superior, 644
 layer of pelvic fascia, 469
 plexus of nerves, 940
 of veins, 700
 Vesicle, auditory, 106
 germinal, 42
 lens, 102
 umbilical, 56
 Vesicles, cerebral, 53, 90
 optic, 94, 102
 Vesico-uterine excavation, 1087, 1184
 Vesiculae seminales, 1169
 applied anatomy of, 1170
 lymphatic vessels of, 735
 structure of, 1170
 vessels and nerves of, 1170
 Vesicular ovarian follicles, 1180
 Vestibular arteries, 1004
 bulb, 1192
 fissure, 996
 ganglion, 1004
 glands, greater, 153, 1192
 lip, 1001
 membrane of Reissner, 999
 nerve, 872, 1004
 nuclei of, 775, 873
 Vestibule, aortic, 561
 of bronchiole, 1042
 of internal ear, 993
 of larynx, 1022
 of mouth, 1046
 of nasal cavity, 945
 of omental bursa, 1092
 of vagina, 1192
 Vestibulospinal tract, 755
 Vestigial fold of pericardium (Marshall), 126, 552
 Vicq d'Azyr, bundle of, 799, 825
 Vidian artery, 590, 596
 nerve, 858
 Viessens, valve of, 780
 Villi of chorion, 65
 of intestine, 1111
 Vincula brevia, 494
 longa, 494
 tendinea, 494, 539
 Visceral arches, 77
 lymph-glands of abdomen and pelvis, 726
 of thorax, 736
 veins, 122
 Visual centres, higher or cortical, 802, 850
 lower, 797, 800, 850
 purple, 14, 960
 Visuopsychic area, 832
 Visuosensory area, 832
 Vitelline circulation, 57
 duct, 56, 57, 133
 fluid, 57
 membrane, 447
 veins, 112, 122
 Vitello-umbilical vein, common, 113

Vitreous body of the eye, 964
 development of, 106
 Vocal cords, false, 1023
 true, 1023
 folds, 1023
 fremitus, 1045
 ligaments, 1023
 process of arytenoid cartilage, 1018
 Vocalis muscle, 1026
 Volar antibrachial muscles, 491
 arch, deep, 623
 superficial, 627
 applied anatomy of, 627
 surface markings of, 1253
 artery, superficial, 622
 branch, deep, of ulnar artery, 626
 of ulnar nerve, 904
 carpal branch of radial artery, 622
 of ulnar artery, 625
 carpal ligament, 500
 network, 622, 625
 digital arteries, common, 627
 proper, 627
 nerves, 903, 904
 veins, 687, 690
 interosseous artery, 627
 nerve, 901
 ligaments, accessory, 627
 metacarpal arteries, 627
 veins, 690
 radiocarpal ligament, 381
 venous arches, 690
 Volaris indicis radialis artery, 623
 Voluntary muscle, 30
 Volvulus, 1124
 Vomer, 222
 ossification of, 222
 Vomeroneasal cartilage, 223, 947
 organs, 82, 947
 Vulva, 1191
 of third ventricle, 803
 Wagner and Meissner, corpuscles of, 1007
 Wallerian degeneration, 40, 754
 Wandering cells, 9
 Weight of brain, 834
 Wens, 428
 Wharton, duct of, 1052
 jelly of, 12, 62
 White commissure of medulla spinalis, 747
 fibres of arcolar tissue, 7
 fibrocartilage, 16
 fibrous tissue, 10
 line of pelvic fascia, 468
 nerve-fibres, 37
 nerve-substance of cerebellum, 778
 of cerebral hemispheres, 827
 of medulla spinalis, 753
 substance of pons, 38, 39
 Whitlow, 505
 Width of face, 261
 Willis, arterial circle of, 601
 cords of, 680
 Windpipe, 1027
 Winged scapula, 271, 435
 Wings of sphenoid, great, 199
 small, 200
 Winslow, foramen of, 136, 1091
